267 STAPHYLOCOCCAL INFECTIONS

CATHERINE LIU, BO SHOPSIN, AND HENRY F. CHAMBERS

DEFINITION

Staphylococci are well adapted as commensals and as pathogens. Coagulase-negative species constitute a significant proportion of the normal human cutaneous microbiome. *Staphylococcus aureus*, a coagulase-positive species, is a nasopharyngeal colonizer in a third of individuals, most of whom will not become infected. As a pathogen, *S. aureus* infections range in severity from relatively trivial skin infections to lethal invasive disease. Coagulase-negative species, which are intrinsically less virulent and less invasive than *S. aureus*, nevertheless are responsible for one in four health care–associated infections, particularly those involving indwelling medical devices. The increasing prevalence of antibiotic-resistant strains of staphylococci has a profound impact on therapy.

The Pathogen

The genus *Staphylococcus* consists of more than 30 distinct species. These organisms have coevolved as normal flora of mammals and birds. These gram-positive spherical cells (i.e., cocci) are 0.5 to 1.5 μm in diameter and divide in multiple orthogonal planes to form clusters resembling grapes when viewed under the microscope. Staphylococci are nonmotile, nonsporulating, hardy organisms that are resistant to desiccation, extremes of pH, and high salt concentrations. Staphylococci can grow under both aerobic and anaerobic conditions. The ability of staphylococci to produce catalase, which is an enzyme that degrades hydrogen peroxide into water and oxygen, definitively distinguishes them biochemically from streptococci and enterococci. The coagulase test is the basis for differentiating *S. aureus* from the numerous other nonpathogenic, coagulase-negative species. Coagulase is a secreted protein that, in the presence of a prothrombin-like plasma protein, converts fibrinogen to fibrin, thereby forming a clot. *S. aureus* produces a variety of other surface proteins (e.g., protein A) that differentiate it from other species.

The staphylococcal chromosome is circular. Approximately 75% of the genes in a given strain constitute a core genome. The remaining 25% contain species-defining elements and mobile genetic elements that have been acquired by horizontal gene transfer and that shape diversity within the species. The *S. aureus* genome is abundant in genes encoding toxins, superantigens, and adhesins, whereas coagulase-negative species contain few adhesin and no toxin or superantigen genes. Genetically, *S. aureus* is sufficiently uniform to classify it as a single species; greater diversity among coagulase-negative species merits their classification as distinct species.

STAPHYLOCOCCUS AUREUS

EPIDEMIOLOGY

S. aureus is maintained in the human population primarily by asymptomatic colonization of the anterior nares, oropharynx, and other moist areas of the body, including the groin, perineum, and perianal area. Infants become colonized by strains from their mothers within weeks of birth. Carriage rates are higher in children than in adults. Higher-than-average *S. aureus* carriage rates are associated with atopic dermatitis, eczema, chronic skin ulcers, and other acute and chronic skin conditions; insulin-dependent diabetes; dialysis; human immunodeficiency virus infection; and injection drug use. Carriers have a several-fold higher risk for developing an *S. aureus* infection compared with noncarriers. The principal mode of transmission of *S. aureus* is direct contact with an infected individual or an asymptomatic carrier, probably through transient hand carriage. *S. aureus* may also contaminate environmental surfaces, where it can persist for days. The role of environmental contamination in transmission is not well defined, but it may be important if heavily contaminated surfaces or materials are contacted. Droplet and aerosol transmission of *S. aureus* plays little, if any, role.

S. aureus is responsible for millions of infections in the United States each year, most of which are community-acquired skin infections. Approximately 5 to 10% of *S. aureus* infections are invasive, three fourths of which are associated with bacteremia. *S. aureus* also causes hundreds of thousands of health care–associated[1,2] (Chapter 261) infections each year, about half of which are caused by methicillin-resistant *S. aureus* (MRSA) in the United States. MRSA strains are now prevalent in the community,[3] but the frequency of and mortality of MRSA have been declining.[4] Although MRSA is now disseminated globally, there is marked geographic variation in MRSA burden that is due mainly to differences in local infection control practices and to pathogen-specific characteristics of the indigenously circulating clones.[5] Community-associated strains circulate in both the community and the health care environments, whereas health care–associated strains are largely restricted to the health care environment. The strains are distinct from each other in several ways (E-Table 267-1). For example, Panton-Valentine leukocidin, which is frequently present in community-associated strains, causes distinct clinical syndromes, such as primary skin abscesses and necrotizing community-acquired pneumonia.

PATHOBIOLOGY

Virulence Factors

S. aureus produces well above 50 virulence factors, including adhesins, toxins, enzymes, surface-bound proteins, and capsule polysaccharides (E-Table 267-2). Genes encoding virulence factors may be located on the chromosome as part of the core genome, within mobile genetic elements (or their remnants, including bacteriophages, pathogenicity islands, and cassettes), or on plasmids. α-Toxin, Panton-Valentine leukocidin, and phenol-soluble modulins, all of which provoke potentially deleterious host inflammatory responses and cause host cells to lyse, appear to be important virulence factors that mediate the severity of disease, especially in community-associated MRSA strains. Protein A, which is a B-cell superantigen that promiscuously triggers B-cell proliferation as well as supraclonal expansion and apoptosis, interferes with the host's antibody-mediated adaptive immunity.

Virulence factors promote binding to host tissues; allow the organism to evade, circumvent, or disrupt host immune responses; and facilitate cell injury and tissue invasion.[6] Variability in both the presence of virulence determinants

Virulence factors promote binding to host tissues; allow the organism to evade, circumvent, or disrupt host immune responses; and facilitate cell injury and tissue invasion.[6] Variability in both the presence of virulence determinants

ABSTRACT

Staphylococcal infections are among the most commonly encountered bacterial infections. *S. aureus* disease occurs by two mechanisms: tissue invasion, which may be local or systemic, and the production of toxins. The latter can occur in the absence of invasive disease in staphylococcal food poisoning and toxic shock syndrome. Skin and soft tissue infections range in severity from impetigo, furuncles, and folliculitis to necrotizing fasciitis and pyomyositis. Systemic infection can take the form of bacteremia, endocarditis, pericarditis, osteomyelitis, and septic arthritis, as well as pulmonary, orthopedic device–associated, central nervous system, and genitourinary infections. The principles of *S. aureus* treatment are source control, by drainage of abscesses and removal of infected foreign material when feasible, as well as systemic antimicrobial therapy.

E-TABLE 267-2 EXAMPLES OF VIRULENCE FACTORS PRODUCED BY *STAPHYLOCOCCUS AUREUS*

ACTIVITY	GENES	PROTEIN OR MOLECULE
Inhibition of antimicrobial peptides	*icaA, icaD, icaB, icaC, icaR*	Polysaccharide intercellular adhesin (PIA)
	isdA, isdB	Iron-regulated surface determinants of *S. aureus* (IsdA and IsdB)
	mprF	Multiple peptide resistance factor (MprF)
	Sak	Staphylokinase
Inhibition of chemotaxis	*chp*	Chemotaxis inhibitory protein of *S. aureus* (CHIPS)
	ecb	Extracellular complement-binding protein (Ecb)
	efb	Extracellular fibrinogen-binding protein (Efb; inhibitor of C5a generation)
	scn	Staphylococcal inhibitor of complement (SCIN)
Inhibition of oxygen-mediated bacterial killing	*crtM, crtN*	Carotenoid pigment, staphyloxanthin (*S. aureus* golden pigment; resistance to reactive oxygen species)
	spn	Staphylococcal peroxidase inhibitor (resistance to reactive oxygen species)
	isdA, isdB	Iron-regulated surface determinants of *S. aureus*, IsdA, and IsdB (promote resistance to neutrophil reactive oxygen species)
	sodA, sodM	Superoxide dismutase, SodA, SodM (promotes resistance to neutrophil reactive oxygen species)
Inhibition of neutrophil function	*cap5* or *cap8*	Capsular polysaccharide (inhibits phagocytosis)
	clfA	Clumping factor A (ClfA; inhibits phagocytosis)
	eap	Extracellular adherence protein (Eap; inhibits leukocyte adhesion)
	hlgA, hlgB, hlgC	Gamma hemolysin subunits A, B, and C; HlgA, HlgB, HlgC (causes cell lysis)
	lukAB, lukED lukSF-PV (Panton-Valentine)	Leukocidins (cause cell lysis)
	psm	Phenol-soluble modulin-like peptides (PSMs; causes cell lysis)
Perturbation of T-cell function	*sea, seb, sec*$_n$, sed, see, seg, seh, sei, sej, sek, sel, sep	Staphylococcal enterotoxins: SEA, SEB, SEC$_n$, SED, SEE, SEG, SEH, SEI, SEJ, SEK, SEL, SEP (superantigens)
	tst	Toxic shock syndrome toxin 1 (TSST-1; superantigen)
Perturbation of B-cell function	*spa*	Protein A (B-cell superantigen)
Adhesion	*cna*	Collagen-binding protein
	fnA, fnB	Fibronectin-binding proteins A and B
	clfA, clfB	Clumping factors A and B (binds platelets and fibrinogen)

and their expression among strains allows extreme diversity among clinical isolates, remarkable adaptability and versatility of *S. aureus* as a pathogen, and a wide spectrum of clinical syndromes. An extensive network of two component response systems, DNA-binding proteins and regulatory RNAs, controls the expression of virulence (and other) factors in response to environmental conditions. Principal among these factors is the accessory gene regulator *agr*, which is a two-component quorum sensing and global gene regulator that coordinately controls the expression of numerous surface and secreted proteins. Mutations in *agr* are associated with loss of virulence.

Biofilm formation, a feature of coagulase-negative infections in particular, occurs in the presence of foreign material, such as vascular catheters or implanted devices. Biofilms are a complex network of extracellular polysaccharides, DNA, and protein in which bacterial cells become embedded, thereby rendering them inaccessible to clearance by host defense mechanisms.[7] Organisms within biofilms tend to be metabolically inactive and show tolerance with reduced susceptibility to the lethal actions of antimicrobial agents.

Mechanisms of Disease

The pathogenesis of invasive *S. aureus* disease usually proceeds from local tissue invasion to systemic infection. This process is dependent on the local and systemic effects of many virulence factors acting in combination. The hallmark lesion in tissues is the abscess, which is a focal collection of pus (liquefied and necrotic host tissue, blood, inflammatory cells, DNA, and cellular debris) and bacterial cells surrounded by an ill-defined layer of edematous and inflamed tissue infiltrated by acute and chronic inflammatory cells.

Host defenses against *S. aureus* tissue infection primarily consist of an intact, normal skin barrier and the innate immune system. Conditions in which these defenses are breached or impaired are associated with increased risk of *S. aureus* infection. Among these conditions are injection drug use (Chapter 365), presence of vascular access devices, burns (Chapter 97), chronic skin diseases, use of systemic steroids, traumatic wounds, minor skin abrasions or trauma, surgical procedures, insulin-dependent and non–insulin-dependent diabetes (Chapter 210), peritoneal dialysis (Chapter 117), hemodialysis (Chapter 117), subcutaneous and intramuscular injections, acupuncture, prosthetic implants, congenital or acquired disorders of neutrophils (e.g., chronic granulomatous disease [Chapter 153]), and advanced age. If the cutaneous barrier is breached, the next line of defense is the innate immune system (Chapter 35). Neutrophils recruited to the site of infection ingest and kill staphylococci.

Staphylococci elaborate numerous virulence factors that specifically thwart each step of the host response. If large numbers of organisms are present, the host response is overwhelmed, infection is not contained, and dissemination occurs. Endothelial cell injury and invasion can also occur. Intracellular organisms and small colony variants within phagocytes and endothelial cells may play a role in relapse and persistent bacteremia by acting as a protected sanctuary against the innate immune host response and antimicrobial therapy. High tissue burdens of organisms and bacteremia are usually, but not always, accompanied by fever, tachycardia, and other signs of the systemic inflammatory response syndrome, including frank septic shock (Chapter 94).

Toxinoses are a separate category of disease for which a toxin is both necessary and sufficient. The three toxin-mediated syndromes, which can occur in the absence of invasive disease, are staphylococcal food poisoning, staphylococcal toxic shock syndrome, and staphylococcal scalded skin syndrome. Staphylococcal food poisoning is caused by the ingestion of a preformed heat-stable enterotoxin. The emetogenic activity of enterotoxin is mediated by the intestinal release of 5-hydroxytryptamine and the stimulation of receptors present on afferent vagal neurons. Toxic shock syndrome is caused by a specific toxin, TSST-1, or other staphylococcal enterotoxins acting as superantigens that bind to major histocompatibility complex class II molecules of antigen-presenting cells and T-cell receptors, thereby stimulating the massive release of cytokines from T cells and resulting in shock and death. Staphylococcal scalded skin syndrome and bullous impetigo are caused by either of two exfoliative toxins, A or B. These toxins are serine proteases that specifically cleave desmoglein 1, which is a desmosomal protein that anchors the overlying superficial epidermis to the stratum granulosum.

CLINICAL MANIFESTATIONS

Skin and Soft Tissue Infections

Skin and soft tissue infections are by far the most common infections caused by *S. aureus;* millions of cases occur annually in the United States (Chapter 408). This heterogeneous group of skin diseases includes impetigo (Fig. 408-1), folliculitis, furuncle (Fig. 408-2), abscess, erysipelas (Fig. 408-4), cellulitis (Fig. 408-3), mastitis (cellulitis of the breast), necrotizing fasciitis, and wound infections. Community-acquired MRSA strains encoding Panton-Valentin leukocidin have been associated with an increased rate of primary skin and soft tissue infections in the United States, and recurrent infections occur in about 20% of individuals.[8]

Impetigo, folliculitis, and furuncle (Chapter 408) are superficial infections; fever and other systemic signs of infection are not present. Impetigo, which is a focal infection of the epidermis, occurs most commonly in children (see Fig. 408-1). The typical lesion, which may be multiple or in clusters, is about 1 cm in diameter, with erythema surrounding a bulla or bullae (caused by the production of exfoliative toxin) that contains cloudy fluid or has a crusty or scabbed-over appearance. Folliculitis is a superficial infection with tender, erythematous, maculopapular or pustular lesions centered around hair follicles. A furuncle is simply a boil, a painful focal collection of pus with surrounding erythema measuring 1 to 2 cm or more in diameter that extends through the dermis into the subcutaneous tissue (see Fig. 408-2). The distinction between a furuncle and an abscess is somewhat arbitrary. Abscesses tend to be larger and deeper and may be associated with systemic signs of infection and bacteremia. Furuncles may extend to fascia or deeper tissues and coalesce into carbuncles.

Erysipelas (see Fig. 408-4) and cellulitis, which are similar in appearance, are painful, warm, indurated, erythematous, nonlocalized infections that may be accompanied by lymphangitis. Cellulitis extends into the dermis and subcutaneous fat; erysipelas is more superficial. Cellulitis due to streptococci (Chapter 269) cannot reliably be distinguished from that caused by *S. aureus* owing to their similar appearance, although associated purulence suggests staphylococcal infection.

Necrotizing fasciitis is an infection of the deep layers of skin and subcutaneous tissues, extending to muscle and along fascial planes. It is associated with systemic toxicity, leukocytosis, and severe pain often out of proportion to the physical findings. The overlying skin may appear to be uninvolved, belying the serious nature of this infection. Necrotizing fasciitis, which is more typically caused by group A streptococci (Chapter 269) or mixed aerobic and anaerobic organisms, has been associated with community MRSA infection.

Pyomyositis (also termed tropical myositis) is a deep abscess or multiple abscesses within skeletal muscle. *S. aureus* is the most common cause. The patient presents with fever, pain, swelling, and induration that can be felt on deep palpation. The overlying skin and soft tissue may appear normal. There is often a history of trauma to the infected area. Although pyomyositis can occur in otherwise normal persons, acquired immunodeficiency syndrome (Chapter 358) and other immunocompromising conditions are predisposing factors. This infection is thought to occur as a consequence of metastatic seeding from a subclinical bacteremia, although blood cultures may not be positive at the time of diagnosis. Computed tomography or magnetic resonance imaging should be obtained to identify lesions. The diagnosis is established by culture of pus collected by needle aspirate.

Secondary *S. aureus* infection due to skin injury is unlinked to Panton-Valentin leukocidin and occurs in a variety of situations such as diabetes, underlying skin diseases, and surgery. *S. aureus* causes 30% of surgical site infections overall in the United States. These infections occur at the site of incision and are associated with significant morbidity, particularly in the setting of a prosthetic device. Signs and symptoms are fever accompanied by erythema, edema, induration, drainage, pain, and tenderness at the surgical site.

Bacteremia

Bacteremia[9] is present in approximately 75% of cases of invasive infection. The most common sources of bacteremia are skin and soft tissue infections, central venous catheters and other intravascular devices, bone and joint infections, pneumonia, and endocarditis. Bacteremia can originate from any source, which may not be obvious in 25% of cases. Once organisms have invaded the bloodstream they can disseminate widely throughout the body, thereby establishing multiple metastatic sites of infection and perpetuating the bacteremia. Fever is usually, but not always, present. Patients with *S. aureus* bacteremia have high rates of organ failure and septic shock (Chapter 94).

Endocarditis

S. aureus, which is the leading cause of both native valve and prosthetic valve endocarditis (Chapter 61), accounts for approximately 30% or more of all cases. Endocarditis may be community-acquired or, increasingly, health care–associated. Risk factors include injection drug use (Chapter 365), diabetes mellitus (Chapter 210), hemodialysis (Chapter 117), presence of a prosthetic valve (Chapter 60) or other implantable intracardiac device, and recent hospitalization. Endocarditis may present as an acute febrile illness with high fever

that develops over a few days. The patient may appear toxic and septic, but some patients have surprisingly few acute symptoms and complain only of protean symptoms such as shortness of breath, malaise, and weakness. The intracardiac source of infection initially may not be evident because a pathologic murmur may not be heard when the patient first presents. A quarter or more of patients have a coincident infection of bone, joint, or skin and soft tissue. The aortic and mitral valves are most commonly involved in native valve infection, but the tricuspid valve can be involved, especially in persons who inject drugs. Systemic embolization to the brain, kidneys, spleen, gut, or other large vessels is clinically evident in about one third of cases. Peripheral manifestations, including Roth spots (Fig. 391-26), Osler nodes (Fig. 61-2), Janeway lesions, splinter hemorrhages (Fig. 39-10), and petechiae (Fig. 61-1), occur with a similar frequency.

Native valve endocarditis in persons who inject drugs involves the tricuspid valve in approximately three quarters of cases. Patients typically have fever, cough, hemoptysis, and pleuritic chest pain as a consequence of hematogenous seeding of the lung and septic emboli from the valve. The chest radiograph may show pulmonary infiltrates, signs of consolidation, or pleural effusion. Multiple, often peripheral, nodular pulmonary infiltrates with cavitation are hallmark features of septic embolization (Fig. 267-1).

Pericarditis

S. aureus is the most common cause of purulent pericarditis (Chapter 62) after cardiac surgery in adults. It may occur by contamination at the time of surgery; by bacteremic seeding from another site of infection; as a complication of endocarditis, paravalvular abscess, or myocardial abscess; or by direct extension of infection from pneumonia, lung abscess, or empyema. The presentation is that of acute pericarditis (Chapter 62), with fever and severe chest pain, tachycardia, and hemodynamic instability. The clinical course may be extremely rapid, terminating in septic shock or cardiac tamponade.

Osteomyelitis

S. aureus is the most common cause of osteomyelitis, both acute and chronic (Chapter 251). Disease arises from hematogenous dissemination or contiguous spread. Hematogenous infection is often monomicrobial. Contiguous infection is often polymicrobial and results from trauma, inoculation during surgery, or soft tissue infection. Acute osteomyelitis—defined as an initial episode with a clinical course of days to weeks, but not months—is manifested with fever and pain at the site of infection. Vertebrae (most commonly lumbar and cervical) are more commonly infected in adults,[10] but adults also can have long bone osteomyelitis, usually from a contiguous focus of infection or at a site of fracture, prior trauma, or orthopedic hardware. Vertebral osteomyelitis[11] is frequently accompanied by paravertebral or epidural abscess (Fig. 267-2; Chapter 382). Back pain accompanied by signs of cord compression, such as radicular pain, sensory loss, lower extremity weakness, urinary retention, and bowel or bladder incontinence, is an emergency.

Septic Arthritis

S. aureus is the most common cause of septic arthritis (Chapter 251), usually as a consequence of bacteremic seeding, trauma, or a surgical procedure. Risk factors include diabetes, recent joint surgery or joint prosthesis (Chapter 255), and rheumatoid arthritis (Chapter 243). Cardinal features are joint pain, history of joint swelling, and fever. Hip, knee, ankle, and wrist are most commonly affected. *S. aureus* also has a predilection for infecting the sternoclavicular, sacroiliac, and symphysis pubis joints. Multiple joints are involved in 5% of cases.

Central Nervous System Infections

S. aureus is an uncommon cause of community-acquired central nervous system infections, such as meningitis (Chapter 381), primary brain abscess (Chapter 382), or subdural empyema. These infections are often associated with endocarditis or a contiguous focus of infection, such as cavernous sinus thrombosis. *S. aureus* is an important cause of nosocomial meningitis after head trauma, craniotomy, or implantation of intraventricular or extraventricular catheters.

Pulmonary Infections

S. aureus is an uncommon cause of community-acquired pneumonia (Chapter 85), accounting for only 1 to 5% of cases but with geographic and seasonal (i.e., increased during influenza season) variability. *S. aureus* pneumonia is usually a fulminant necrotizing pneumonia accompanied by evidence of cavitation on chest radiographs.[12]

Hospital-acquired and ventilator-associated pneumonias (Chapter 91) often are caused by *S. aureus* and community-acquired or hospital-acquired MRSA strains. Patients with traumatic or medical brain injury (e.g., stroke, hemorrhage) are particularly prone to early colonization and subsequent pneumonia by this pathogen.

Lung abscess (Chapter 78) and pleural empyemas (Chapter 86) most commonly are caused by oral anaerobic bacteria but are occasionally caused by *S. aureus*. The clinical course may be subacute or even indolent. Empyema occurs as a complication of prior chest tube placement, surgery, trauma, staphylococcal pneumonia, or tricuspid valve endocarditis.

Orthopedic Device–Associated Infections

S. aureus is second only to coagulase-negative staphylococci as a cause of infections of prosthetic joints and orthopedic implants, but it is the most common cause within the first 12 weeks of surgery. The presentation may be acute, with joint pain, evidence of arthritis, fever, and systemic signs of infection. Alternatively, the infection may run a more chronic course, with pain and loosening of the prosthesis but little or no fever.

Genitourinary Infections

Genitourinary infections (Chapter 263) arise by hematogenous dissemination or as an ascending infection, usually as a result of instrumentation, urinary catheterization, or surgery. These infections include cystitis, pyelonephritis,

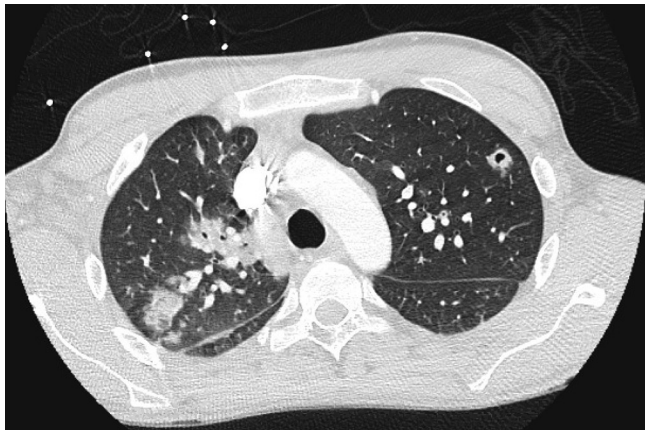

FIGURE 267-1. Computed tomography (CT) of the chest shows multiple nodular pulmonary lesions with areas of cavitation, suggestive of septic embolization, in a patient with tricuspid valve *S. aureus* endocarditis.

FIGURE 267-2. Noncontrast, non–fat-saturated, T1-weighted, sagittal sequence shows discitis, osteomyelitis, prevertebral and epidural abscess, and cord compression in a patient with S. aureus infection of the cervical spine.

microabscess, perinephric abscess, prostatitis, and prostatic abscess. *S. aureus* can also be a contaminant introduced during the collection of urine from a patient with asymptomatic vaginal or perineal colonization.

DIAGNOSIS

S. aureus infection is diagnosed by isolating the organism in culture of blood, tissue, or pus or by detecting it on a nucleic acid amplification test. Culture remains the "gold standard." Gram stain is useful for making a presumptive diagnosis of staphylococcal infection and should be performed whenever possible to look for gram-positive cocci in pus, bone or tissue samples, respiratory secretions, or body fluids such as cerebrospinal fluid, pleural or pericardial fluid, synovial fluid, or urine. Failure to isolate the organism in culture is strong evidence against *S. aureus* infection unless a patient is being actively treated with an antibiotic; even then, infected sites may remain culture positive for several days. The specificity of isolating *S. aureus* from blood or other sterile body sites is essentially 100%.

Bacteremia and Endocarditis

When blood cultures are positive, even if the primary source is known, the patient may have endocarditis and metastatic foci of infection.[13] Follow-up blood cultures should be obtained within 24 hours to document clearance. Persistent bacteremia is suggestive of endovascular infection, and failure to clear blood cultures after 2 to 3 days of appropriate therapy is associated with increased risk of mortality.[14,15] Echocardiography is generally recommended in all cases of *S. aureus* bacteremia to look for valvular vegetations or other signs of endocarditis. Transesophageal echocardiography, which is more sensitive than transthoracic echocardiography, is the preferred modality if the suspicion of endocarditis is moderate or high.[16] Factors associated with a low risk of endocarditis and in which a transesophageal echocardiogram may not be necessary include sterile follow-up blood cultures after 1 to 2 days of therapy, absence of an intracardiac device (e.g., pacemaker, prosthetic valve), acquisition in a health care setting with immediate source control (e.g., catheter removal), and absence of a secondary or metastatic focus of infection. Clinical prediction tools can stratify patients and identify those at low risk for endocarditis in whom TEE may be unnecessary.[17] Computed tomography or magnetic resonance imaging should be considered if signs and symptoms point to deep tissue abscesses or osteomyelitis.

Pericarditis

Staphylococcal pericarditis (Chapter 62) is suspected based on an enlarging cardiac silhouette in the context of an adjacent pneumonia or bacteremia. Ultrasonography can confirm the presence of an effusion, and pericardiocentesis can establish the microbiologic diagnosis.

Osteomyelitis and Septic Arthritis

MRI is the preferred imaging technique, particularly for vertebral osteomyelitis. However, the diagnosis of osteomyelitis is established via culture obtained from bone biopsy or blood. The diagnosis of septic arthritis is established by culture and by analysis of synovial fluid, in which the white blood cell count typically exceeds 25,000/μL, with 90% neutrophils. Blood cultures are positive in 30 to 50% of cases, organisms are seen on Gram stain of synovial fluid in about 50% of cases, and synovial fluid culture is almost always positive.

CNS Infections

The diagnosis of neurosurgical infections due to *S. aureus* is typically established by deep cultures obtained from an infected surgical wound or craniotomy site. For patients in whom meningitis or ventriculitis is a concern, the cerebrospinal fluid (CSF) should be sampled by lumbar puncture, a ventriculoperitoneal shunt, or an extraventricular drain if present.

Pneumonia

The diagnosis of staphylococcal pneumonia is readily established by examination of a Gram stain and culture of sputum, tracheal aspirate, or lavage fluid (obtained to avoid oropharyngeal contamination), which typically shows organisms and numerous neutrophils. The culture is less specific than the Gram stain because it can be positive in colonized patients, but it is highly sensitive.

Orthopedic Device–Related Infections

The diagnosis of a prosthetic joint infection is made by sampling the synovial fluid for cell count with differential, Gram stain, and culture. Additionally, intraoperative cultures demonstrating growth of *S. aureus* confirm the diagnosis.

Genitourinary Infections

When urinary tract infection is suspected, urine culture is required. Contamination should be suspected if the urine colony counts are low, repeated urine cultures are negative, pyuria is absent, and there are no signs or symptoms of urinary tract infection. If contamination seems unlikely and there is no well-documented history of an event that could lead to ascending infection, hematogenous dissemination should be suspected. Blood cultures should be obtained to determine whether there is ongoing bacteremia and appropriate imaging studies performed to identify a deep focus of infection and the presence of renal and perinephric abscesses.

Susceptibility Testing

The choice among curative antibiotics (see Table 267-2) is critical for successful treatment and must be guided by susceptibility testing. The critical determination is whether the isolate is methicillin resistant (i.e., resistant to β-lactam antibiotics). Clindamycin, which is usually active against community strains, is less reliable for hospital strains. Resistance to vancomycin, daptomycin, telavancin, linezolid, or ceftaroline is rare, but susceptibility testing is important for these antibiotics, particularly if the patient has had prior exposure to the drug. Strains with even intermediate susceptibility to vancomycin (4 or 8 μg/mL), which account for 1 to 3% of MRSA isolates, should be considered resistant because this finding is highly predictive of failure with vancomycin treatment. Persistent endovascular infections are particularly likely to have reduced susceptibility to vancomycin and daptomycin, in part because these drugs have poor penetration into vegetations and blunted bactericidal activity against slowly dividing organisms at high inocula.

TREATMENT

The two principles of therapy for *S. aureus* infections are (1) source control by elimination of abscesses and infected foreign material whenever feasible and (2) administration of systemic antimicrobial therapy. Infections at different sites are managed differently in terms of local source control, as well as the type, route, and duration of antibiotics (see Table 267-2). Lack of adequate source control, such as an undrained focus of infection, retention of an infected foreign body, or endovascular infection, is the most common reason for unsatisfactory clinical response, treatment failure, or relapse.

Approach to Specific Clinical Syndromes

Skin and Soft Tissue Infections

Both impetigo and folliculitis readily respond to local measures, such as application of soap and water, topical antibiotics, or antiseptics; systemic antimicrobial therapy (see Table 267-2) may be indicated for extensive or refractory infections. A furuncle may drain spontaneously with application of hot compresses or can be surgically drained with simple incision and drainage. Antimicrobial therapy improves short-term cure rates and reduces rates of recurrence. Large abscesses and carbuncles, particularly in the presence of fever and other systemic signs of infection, require surgical drainage and systemic antimicrobial therapy. Unless accompanied by bacteremia, the duration of treatment for abscesses following incision and drainage is 5 to 7 days, guided by clinical response. Cellulitis should be treated with systemic antimicrobial therapy; longer durations of up to 12 days may be required for hospitalized patients with severe cellulitis because relapse rates are higher with 6 days of therapy.[A1]

Necrotizing fasciitis requires immediate surgical intervention for débridement of involved tissue. For pyomyositis, surgical or percutaneous drainage should be performed, and systemic antimicrobial therapy is indicated.

Superficial surgical site infections respond to removal of stitches, débridement of devitalized tissue, opening of the wound to allow drainage, and a short course of antimicrobial therapy. Deeper infections may require more extensive débridement and prolonged courses of therapy, particularly if bone or a prosthetic device is involved. Removal of infected prosthetic material or a foreign body greatly increases the chance of cure.

Bacteremia and Endocarditis

Source control is the cornerstone of management and therapy. Both primary and secondary foci of infection should be identified and eliminated whenever possible because they may lead to treatment failure or relapse when antimicrobial therapy is discontinued. Antimicrobial therapy (see Table 267-2) should always be administered. A shorter duration of therapy (i.e., 14 days) is appropriate for uncomplicated bacteremia (Table 267-1). Longer courses of 4 to 6 weeks are recommended for the treatment of bacteremia complicated by slow resolution or the presence of metastatic infection; 6 weeks of therapy is recommended for endocarditis. Monotherapy with vancomycin is as good as combination therapy with fewer adverse effects.[18] For native valve endocarditis, valve replacement is indicated for heart failure (Chapter 61), myocardial abscess, severe valvular disease, or a vegetation >10 mm. Although prosthetic valve endocarditis can

TABLE 267-1 CRITERIA FOR DIAGNOSIS OF UNCOMPLICATED *STAPHYLOCOCCUS AUREUS* BACTEREMIA*

Resolution of fever and systemic signs of infection by day 3 of therapy
Sterile blood cultures within 1-2 days of initiation of antimicrobial therapy
Presence of an identifiable and easily removable focus of infection
Prompt removal of the primary focus of infection
No echocardiographic or clinical signs of endocarditis
No osteomyelitis
No hematogenous secondary foci of infection
No preexisting valve abnormalities predisposing to endocarditis (e.g., prosthetic valve, rheumatic heart disease, bicuspid aortic valve)
No implanted prosthetic device (e.g., prosthetic hip)

*Uncomplicated *S. aureus* bacteremia can be treated with a shorter course of antibiotics (see text).

be managed medically in some cases, outcomes tend to be worse, and surgery and valve reimplantation are usually required to cure the infection or to manage its complications.

Pericarditis

For staphylococcal pericarditis, immediate drainage of the infected pericardial space and administration of systemic antimicrobial therapy are indicated. Purulent pericarditis due to *S. aureus* should be managed as a complicated infection with 4 to 6 weeks of antibiotic therapy based on the adequacy of drainage and clinical response. Pericardiocentesis can provide temporary decompression of the pericardial space, but definitive therapy requires surgical or continuous tube drainage (Chapter 62).

Osteomyelitis and Septic Arthritis

For osteomyelitis, antibiotic management in conjunction with surgical débridement to remove necrotic bone and devitalized tissue is the mainstay of therapy. If source control is adequate, the recommended duration of therapy for osteomyelitis is 6 to 8 weeks, with 8 weeks preferred for MRSA infection. Longer courses may be indicated in patients who have significant residual infected bone or undrained paravertebral abscesses. The duration of therapy must be tailored under expert guidance depending on individual circumstances and whether source control has been achieved. For septic arthritis (Chapter 251), both antimicrobial therapy (see Table 267-2) and drainage of the infected joint (by repeated needle aspiration, by arthrotomy, or arthroscopically) are required to prevent destructive arthritis. Patients with *S. aureus* septic arthritis are typically treated with 3 to 4 weeks of antibiotic therapy.

CNS Infection

For patients with concern for a craniotomy site infection, subdural empyema, or spinal epidural abscess (Chapter 382), magnetic resonance imaging should be performed as soon as possible to define the location and extent of infection, and neurosurgical consultation should be obtained in anticipation of surgical decompression and drainage. The duration of treatment is typically 4 to 6 weeks but should be tailored based on clinical response and adequacy of source control under expert guidance.

For patients who have meningitis associated with a CNS shunt, shunt removal is recommended, with documentation of negative cultures prior to replacement of the shunt. A 10-day course of therapy after CSF cultures are negative is suggested.

Staphylococcal Pneumonia

When a patient with antecedent or concomitant influenza requires admission to an intenstive care unit (ICU), community-acquired staphylococcal pneumonia should be considered, and coverage for MRSA strains should be included in the empirical regimen for severe pneumonia (see Table 267-2). Coverage for *S. aureus* can be discontinued if the organism is not isolated in culture or not detected by nasal swab culture or PCR.[19] Empyemas (Chapter 86) require drainage and antimicrobial therapy. The usual duration of therapy for *S. aureus* pneumonia is 7 to 14 days, but longer durations of up to 4 weeks are indicated for patients with accompanying bacteremia or empyema.

Orthopedic Device–Related Infection

Formation of biofilm makes treatment of device infections challenging.[20] Intraoperative inspection, débridement, and hardware retention may be appropriate for infections of less than 3 weeks in duration or occurring within the first month of implantation. Otherwise, débridement and removal of the prosthesis or implant in conjunction with antimicrobial therapy offer the best chance of cure. The approach can either be a one-stage procedure, in which the infected prosthesis or implant is removed and immediately replaced, or a two-stage procedure, in which the device is removed and replaced after completion of a 6-week course of antimicrobial therapy (see Table 267-2). The duration of therapy for orthopedic device–related infections is dependent on the surgical management approach, guided by expert consultation.

Urinary Tract Infections

The management of staphylococcal urinary tract infections is dependent upon the source of infection. For patients who have a catheter-associated urinary tract infection, the catheter should be removed if no longer needed and be replaced by intermittent catheterization. If the patient requires an indwelling catheter, catheter exchange should be performed. The patient can be treated with an oral agent to which the organism is susceptible for a duration of 7 to 10 days. For patients with concern for a systemic infection, a hematogenous source of bacteriuria, or a more complicated urinary tract infection (e.g., perinephric abscess, prostatitis), a longer duration of therapy under expert guidance is indicated based on the diagnostic evaluation and response to therapy.

Antibiotic Selection

The most important consideration in selecting an antibiotic is susceptibility of the *S. aureus* isolate to β-lactams. For invasive infections, a penicillinase-resistant penicillin—for example, nafcillin (2 g every 4 hours IV), oxacillin (2 g every 4 hours IV), or a cephalosporin (e.g., cefazolin 2 g every 8 hours IV)—is the agent of choice for the treatment of methicillin-susceptible *S. aureus* (MSSA) infections; no other antibiotic, including vancomycin, is as safe or as effective as a β-lactam.[21] ß-Lactams primarily used for treatment of invasive staphylococcal infections include penicillinase-resistant pencillins, cefazolin, or penicillin (for non-penicillinase-producing, penicillin-susceptible strains). Ceftaroline, which is a β-lactam antibiotic with activity against MSSA and MRSA, has been used as salvage therapy either as monotherapy or in combination with another agent for treatment of invasive MRSA infections under expert guidance.

Methicillin-resistant strains are cross-resistant to all currently available β-lactams, except for ceftaroline (dose of 600 mg IV every 12 hours), which is indicated to treat skin and skin structure infections caused by methicillin-resistant strains. Otherwise, a β-lactam should not be used to treat infections known or suspected to be caused by a methicillin-resistant strain.

For invasive infections caused by MRSA, vancomycin is still a drug of choice. It must be administered intravenously; doses of 30 to 60 mg/kg/day, adjusted on the basis of renal function, are recommended to achieve a 24-hour area under the curve of drug concentration over time of 400 to 600 μg × h/mL for patients with bacteremia, endocarditis, or other serious infection.[22] Daptomycin is an alternative to vancomycin for the treatment of invasive MRSA infections, including bacteremia and endocarditis. Some authorities recommend higher doses of daptomycin (e.g., 8 to 12 mg/kg/day), particularly when the infection has failed to respond to vancomycin. For patients who have a serious β-lactam allergy (e.g., anaphylaxis) and invasive methicillin-susceptible *S. aureus* infection, vancomycin and daptomycin are alternative agents.

TOXIN-MEDIATED STAPHYLOCOCCAL DISEASES

Toxin-mediated staphylococcal diseases are caused by the ingestion of preformed toxin or the elaboration of toxin by *S. aureus* from a site of colonization or infection.

Staphylococcal Food Poisoning

Staphylococcal food poisoning is a gastroenteritis caused by the ingestion of enterotoxin produced in food contaminated with *S. aureus* from an infected or colonized food handler.[23] When contaminated food is kept at room temperature for several hours, organisms replicate and produce a heat-stable toxin that is not inactivated by cooking or digestive enzymes. Nausea, vomiting, abdominal pain, and diarrhea occur within 2 to 6 hours of eating the contaminated food, but fever is absent.

TREATMENT AND PROGNOSIS

Antibiotics have no role in therapy, which consists of fluid replacement to prevent dehydration. The illness is self-limited, generally persisting for no more than 1 day. Infants, small children, and the elderly are more severely affected and may require intravenous fluids.

Toxic Shock Syndrome

Staphylococcal toxic shock syndrome (Chapter 406) is caused by colonization or infection with a strain that elaborates a specific toxin, toxic shock syndrome toxin-1 (TSST-1), or another staphylococcal enterotoxin. Toxic shock syndrome toxin-1 is responsible for 100% of cases that are associated with tampon use and menstruation.[24] TSST-1 and other staphylococcal enterotoxins (SEA, SEB, and SEC) are responsible for nonmenstrual toxic shock syndrome, which is characteristically associated with an identifiable focus of infection, usually of the skin.

The diagnosis is clinical, defined by fever, erythroderma (Fig. 403-5), hypotension, involvement of three or more organ systems (renal, hematologic,

TABLE 267-2 TREATMENT OF *STAPHYLOCOCCUS AUREUS* INFECTIONS

CLINICAL SYNDROME	TREATMENTS FOR METHICILLIN-SENSITIVE *S. AUREUS*[*,†]	TREATMENTS FOR METHICILLIN-RESISTANT *S. AUREUS*[*]	COMMENTS
Skin and Soft Tissue Infection, *Oral therapy*	Cephalexin 500 mg PO qid Dicloxacillin 500 mg PO qid TMP-SMX 1-2 DS tab PO bid Doxycycline 100 mg PO bid Minocycline 100 mg PO bid Clindamycin 300-450 mg PO tid	*Preferred agents:* TMP-SMX 1-2 DS tab PO bid Doxycycline 100 mg PO bid Minocycline 100 mg PO bid Clindamycin 300-450 mg PO tid *Alternative agents:* Linezolid 600 mg PO bid Tedizolid 200 mg PO qd	Incision and drainage is a mainstay of treatment for patients with abscesses, but adjunctive antimicrobial therapy improves cure rates even for simple abscesses.[A2,A3] Oral therapy can be used in mild, localized infection without systemic symptoms. Parenteral therapy should be considered in patients with systemic toxicity, extensive soft tissue involvement, or progressive infection despite oral therapy.
Skin and Soft Tissue Infection, *Parenteral therapy*	Cefazolin 1 g IV q8h Nafcillin 1-2 g IV q4h	*Preferred agent:* Vancomycin 15-20 mg/kg IV q8-12h *Alternative agents:* Daptomycin 4 mg/kg IV qd Ceftaroline 600 mg IV q12h Dalbavancin: 1500 mg IV × 1 Linezolid 600 mg IV q12h Oritavancin 1200 mg IV × 1	Local rates of resistance should be considered when choosing empiric therapy. Cefazolin is associated with fewer treatment-related adverse events when compared with nafcillin. Use of alternative oral agents should be considered for methicillin-resistant *S. aureus* skin and soft tissue infections on an individual basis. Listed parenteral alternative agents are noninferior to vancomycin but not superior to it.[A4] Use of alternative parenteral agents for methicillin-resistant *S. aureus* should be considered on an individual basis, taking into account cost, logistics of administration, and side effect profiles.
Bacteremia and Endocarditis	Cefazolin 2 g IV q8h Nafcillin 2 g IV q4h	Vancomycin 15-20 mg/kg IV q8-12h Daptomycin 8-10 mg/kg IV qd	For patients with high inoculum infections such as endocarditis, nafcillin is recommended as initial therapy. In patients with methicillin-sensitive *S. aureus* bacteremia without endocarditis, cefazolin is at least as effective as antistaphylococcal β-lactams, with fewer treatment-related adverse events. Alternative agents may be considered in the setting of vancomycin treatment failures, which can occur even if the strain is susceptible (minimal inhibitory concentration [MIC] ≤2 μg/mL). Possible explanations include an undrained focus of infection, vancomycin's slowly bactericidal activity, or heteroresistance, in which a small fraction of the population of organisms requires a higher MIC. Combination regimens including aminoglycosides or rifampin are not recommended in *S. aureus* bacteremia and native valve endocarditis because of increased toxicity without improved outcome.[A5–A7] Adding an antistaphylococcal β-lactam to standard therapy with vancomycin or daptomycin does not significantly improve outcomes.[A8] Combination therapy may be considered as salvage therapy in patients who do not respond to standard regimens, with the guidance of expert consultation. The role of long-acting agents such as dalbavancin in treatment of bacteremia is under investigation.
Pericarditis	Cefazolin 2 g IV q8h Nafcillin 2 g IV q4h	Vancomycin 15-20 mg/kg IV q8-12h Daptomycin 8-10 mg/kg IV qd	
Bone and Joint Infections	*Parenteral therapy* Cefazolin 2 g IV q8h Nafcillin 2 g IV q4h *Oral therapy* Levofloxacin PO 500-750 mg qd plus rifampin 300-450 mg PO bid TMP-SMX 3.5-4 mg/kg q8-12 plus rifampin 300-450 mg PO bid Clindamycin 600 mg PO q8h	*Parenteral therapy* Vancomycin 15-20 mg/kg IV q8-12h Daptomycin 8-10 mg IV q24h *Oral therapy* Levofloxacin PO 500-750 mg qd plus rifampin PO 300-450 mg qd TMP-SMX 3.5-4 mg/kg q8-12 plus rifampin 300-450 mg PO qd Clindamycin 600 mg PO q8h Linezolid 600 mg PO q12h	Parenteral (initial parenteral followed by highly bioavailable oral antimicrobial therapy) or highly bioavailable oral therapy may be selected based on in vitro susceptibility and on individual circumstances, such as the presence of concurrent bacteremia, surgical débridement, and comorbid conditions. When fluoroquinolones are used as monotherapy, resistance may emerge, so the addition of rifampin is recommended. Linezolid may be considered in the initial course of therapy if other agents cannot be used. Prolonged use of linezolid is limited by bone marrow suppression, peripheral and optic neuropathy, and lactic acidosis.
CNS Infections	Nafcillin 2 g IV q4h	Vancomycin 15-20 mg/kg IV q8-12 h	For MRSA infections, vancomycin is considered the standard of care, but it penetrates the CSF poorly (approximately 1% and 5% in uninflamed and inflamed meninges, respectively). Cefazolin achieves poor CSF concentrations and should not be used for treatment of meningitis/ventriculitis. Limited data suggest benefit of adjunctive use of rifampin for CNS infections because it achieves bactericidal concentrations in the CSF. The addition of rifampin 600 mg qd or 300-450 mg bid, if the organism is susceptible, may be considered in combination with other agents for staphylococcal meningitis and ventriculitis. For patients who have intracranial hardware, such as a CSF shunt or drain that cannot be removed, rifampin is recommended in conjunction with other antistaphylococcal therapy. Data on other medications for CNS infections are limited. Linezolid has good CSF penetration (~66%) and is the preferred second-line treatment if vancomycin cannot be used.

TABLE 267-2 TREATMENT OF *STAPHYLOCOCCUS AUREUS* INFECTIONS—cont'd

CLINICAL SYNDROME	TREATMENTS FOR METHICILLIN-SENSITIVE *S. AUREUS**,†	TREATMENTS FOR METHICILLIN-RESISTANT *S. AUREUS**	COMMENTS
Pneumonia	Cefazolin 2 g IV q8h Nafcillin 2 g IV q4h Clindamycin 600 mg IV/PO q8h Linezolid 600 mg IV/PO q12h	Vancomycin 15-20 mg/ kg IV q8-12h Linezolid 600 mg IV/PO q12h	Clinical trials have found no differences in outcomes when patients with MRSA nosocomial pneumonia receive vancomycin or linezolid.[A9] Daptomycin should not be used to treat primary staphylococcal pneumonia because it is inactivated by pulmonary surfactant. It is indicated, however, for the treatment of hematogenous pneumonia, as occurs in tricuspid valve endocarditis or septic pulmonary embolization. Clindamycin and linezolid are protein synthesis inhibitors and have been shown in in vitro and animal models to inhibit toxin production. Further clinical studies are needed to define their role and that of intravenous immunoglobulin in toxin-mediated infections, such as community-acquired necrotizing staphylococcal pneumonia.
Orthopedic Device–Related Infections	*Parenteral therapy* Cefazolin 2 g IV q8h plus rifampin 300-450 mg PO bid Nafcillin 2 g IV q4h plus rifampin 300-450 mg PO bid *Oral therapy* Levofloxacin PO 500-750 mg qd plus rifampin 300-450 mg PO 450 bid TMP-SMX 3.5-4 mg/kg q8-12 plus rifampin 300-450 mg PO bid	*Parenteral therapy* Vancomycin 15-20 mg/kg IV q8-12h plus rifampin 300-450 mg PO bid Daptomycin 8-10 mg IV q24h plus rifampin 300-450 mg PO bid *Oral therapy* Levofloxacin PO 500-750 mg qd plus Rifampin PO 300-450 mg bid TMP-SMX 3.5-4 mg/kg q8-12 plus rifampin 300-450 mg PO bid	Surgical débridement with removal of hardware or two-stage exchange (in the case of prosthetic joint infections) offers the best chance of success. For orthopedic device–related infections with hardware retention or single-stage exchange, the addition of rifampin is recommended.
Genitourinary Infections	Based on susceptibility testing and clinical situation under expert guidance.	Based on susceptibility testing and clinical situation under expert guidance.	*S. aureus* is uncommonly isolated in urine culture and may represent asymptomatic bacteruria, cystitis, upper tract infection, or hematogenous seeding. No clinical trials to guide therapy. Blood cultures should be obtained if there is concern for systemic infection or upper urinary tract involvement, and treatment should be initiated with the same regimen as for bacteremia/endocarditis while awaiting blood cultures and further diagnostic results. For urinary catheter–associated infections, catheter removal (or exchange if still needed) is recommended. Cystitis can be treated with an oral agent to which the isolate is susceptible.

*Doses are for patients with normal renal function and may require adjustment for those with renal impairment.
†For patients with MSSA infections who are allergic to or intolerant of β-lactams, agents active against MRSA are effective alternatives.

hepatic, pulmonary, gastrointestinal, muscle, central nervous system, mucous membranes), and desquamation, especially of the palms and soles, 1 to 2 weeks after the onset of illness. Bacteremia is present in only 5% of cases.

TREATMENT AND PROGNOSIS

Treatment consists of systemic antimicrobial therapy as for bacteremia (see Table 267-2), removal of the source of toxin production, and treatment of septic shock (Chapter 94). The case fatality rate is about 5%.

Scalded Skin Syndrome

Infection or, rarely, colonization with an *S. aureus* strain that produces exfoliative toxin A or B may cause staphylococcal scalded skin syndrome,[25] which is a disease primarily of infants but occasionally seen in adults (Fig. 267-3), and bullous impetigo (Fig. 406-18), which is a pustular skin lesion. The appearance is that of a scald, burn, or blister. The diagnosis is based on history and a physical examination showing characteristic pain, erythema, blistering, and desquamation. A positive Nikolsky sign (sloughing of skin in response to slight mechanical pressure) may be observed. Cultures should be obtained from areas where purulent drainage is present or from common sites of *S. aureus* colonization (e.g., nares, nasopharynx) to confirm the diagnosis. The differential diagnosis of staphylococcal scalded skin syndrome includes drug reaction (Chapter 407), toxic epidermal necrolysis (Chapter 406), Kawasaki disease (Chapter 406), and pemphigus foliaceus (Chapter 406). Treatment is as for bacteremia (see Table 267-2).

FIGURE 267-3. Scalded skin–type lesions with multiple ruptured bullae and desquamation in a patient with aortic valve endocarditis caused by an exfoliative toxin–producing strain of S. aureus.

PREVENTION

Infection prevention strategies are critical to limiting both community-acquired and health care–associated staphylococcal infections. Because infections may

arise from the patient's resident flora or be acquired from direct contact with a contaminated source (e.g., a wound or dressing, the skin or hands of an asymptomatically colonized individual, or a contaminated health care provider), the most effective strategy is adherence to principles of basic infection control. The key intervention is hand hygiene, whether it is handwashing or use of an alcohol-based hand rub. Barrier precautions (gloves and gowns), which are important for minimizing contact with infected wounds, contaminated secretions, and dressings, should be used to interrupt transmission during uncontrolled outbreaks. The role of contact precautions outside of these scenarios is more controversial, with some studies demonstrating a benefit in reducing MRSA transmission while others do not.[26] For patients undergoing surgical procedures, surgical hand and surgical site antisepsis, aseptic surgical technique, and antimicrobial prophylaxis are important preventive measures.

Another potentially effective means of preventing infection is screening and decolonization of *S. aureus* carriers.[27] Studies to determine whether screening, decolonization, and isolation actually prevent MRSA infection have had mixed results. In the ICU setting, universal decolonization with 2% chlorhexidine baths, mouthwash, or showers plus 2% intranasal mupirocin ointment is more effective than targeted screening and decolonization or education alone in reducing rates of MRSA infection. Postdischarge decolonization of MRSA carriers with topical chlorhexidine and mupirocin twice monthly for 6 months also can reduce the risk of MRSA infection in the year after discharge compared with education alone.[A10] However, daily bathing with chlorhexidine alone does not reduce the incidence of health care–associated infections in critically ill adults in ICUs.[A11]

Decolonization may be considered in two other settings: prevention of recurrent skin and soft tissue infection and prevention of surgical site infections. The best-studied regimens are topically applied mupirocin nasal ointment and daily bathing with chlorhexidine soap for 5 to 10 days. Household decolonization may be considered in households with young children, where there are multiple family members with infections, or if there is ongoing transmission despite optimization of wound care and hygiene measures. The number of surgical site *S. aureus* infections can be reduced by the rapid screening of nasal carriers by real-time PCR assay followed by the decolonization of carriers with mupirocin nasal ointment and chlorhexidine soap.

PROGNOSIS

Prognosis of *S. aureus* infections and outcomes depend on the site of infection, adequacy of source control, presence of comorbidities (e.g., diabetes, immunosuppression, underlying cardiac, renal, or liver disease), presence and duration of bacteremia, presence of secondary foci of infection, presence of severe sepsis or septic shock, antibiotic effectiveness, and duration of therapy for complicated disease. Methicillin resistance is a risk factor for poorer outcome largely because of its health care association and occurrence in a population that is elderly and in which comorbid medical illnesses are prevalent and possibly because less effective antibiotics (non–β-lactams) are used to treat these infections.

Historically, untreated *S. aureus* bacteremia was lethal in 85% or more of cases. Antibacterial therapy, 4 to 6 weeks or longer for complicated bacteremia or infections of deep tissues, and recognition of the importance of source control have dramatically improved outcome, but mortality remains high. In *S. aureus* bacteremia, death occurs in 10 to 30% of cases.[28] Several studies have shown a strong link between elevated host interleukin-10 serum concentrations (>5 to 8 pg/mL) on clinical presentation and mortality in patients with *S. aureus* bacteremia. In patients with severe sepsis, septic shock, or endocarditis, morbidity and mortality are high, in part due to the occurrence of these infections in older patients, many of whom have comorbid medical conditions and impaired innate immunity. Mortality from endocarditis is in the 20 to 40% range. Strokes occur in approximately 20% of patients, and heart failure occurs in 40 to 50%. *S. aureus* prosthetic valve endocarditis is associated with a 40% or higher in-hospital mortality.

Staphylococcal pericarditis (Chapter 62) is associated with high morbidity due to complications such as cardiac tamponade, with mortality rates ranging from 20 to 40%. For hospital-acquired staphylococcal pneumonia, the mortality can be as high as 40 to 50%, reflecting the virulence of the organism and the comorbid conditions that contribute to poor outcomes.

For *S. aureus* osteomyelitis (Chapter 251), outcomes are highly variable and dependent on factors such as completeness of surgical débridement, the anatomic location of bony involvement, the presence of concurrent bacteremia, the underlying comorbid conditions, and vascular insufficiency.

Septic arthritis (Chapter 251) is associated with adverse joint outcomes in about one-third of patients, with in-hospital mortality rates of about 10%. Factors associated with worse outcomes include older age, pre-existing joint disease, and polyarticular joint infection.

For CNS infections due to *S. aureus*, outcomes are dependent on the nature of and extent of infection and surgical management (e.g., bone flap removal for craniotomy infections). Mortality associated with *S. aureus* meningitis ranges from about 25 to 45% and is higher in patients who have a hematogenous source compared with a postoperative source.

For orthopedic-device infections, outcomes are dependent on type of surgical procedure. For patients who have prosthetic joint infections, two-stage exchange arthroplasty is generally associated with improved outcomes when compared with débridement and retention of prosthesis.

For ascending catheter-associated urinary tract infections, outcomes are generally favorable with catheter removal and antibiotic therapy. For patients whose bacteriuria reflects hematogenous dissemination or a more complicated infection, outcomes are dependent on management of bacteremia and underlying source.

Skin infections are generally cured with appropriate antibiotic therapy accompanied by incision and drainage. Depending on the depth and severity of infection, scarring may occur.

COAGULASE-NEGATIVE STAPHYLOCOCCI

More than 30 different species of coagulase-negative staphylococci have been identified, and about half of these colonize humans. *Staphylococcus epidermidis* is the species that most commonly causes infection.[29] Coagulase-negative staphylococci infrequently cause infection unless there is a foreign body in place, and although bacteremia occurs, metastatic seeding of secondary sites of infection is distinctly uncommon. Coagulase-negative staphylococci are often resistant to methicillin and multiple other antibiotics, and they are an important reservoir of drug resistance elements that are horizontally transferrable to *S. aureus*. They are the most common cause of health care–associated infections overall in the United States (Chapter 261), they account for one third of central line–associated bloodstream infections, and they are the second most common cause of surgical site infections, particularly when a prosthetic device or other foreign material has been implanted. Coagulase-negative staphylococci, most especially *S. lugdunensis*, have been reported to cause native valve endocarditis. *S. epidermidis* and other coagulase-negative species account for about a third of cases of prosthetic valve endocarditis, particularly in cases with onset less than 2 months after valve implantation. Despite their relatively low virulence compared with *S. aureus*, mortality rates of patients with left-sided endocarditis caused by coagulase-negative staphylococci are similar to those caused by MRSA. Mortality is associated with β-lactam resistance (true for >80% *S. epidermidis*), again raising the concern of the inferiority of non–β-lactam drugs in the treatment of endovascular infections. Infections are often indolent, causing little in the way of fever or systemic signs of infection, but they may also be acute and life-threatening, as in the case of prosthetic valve endocarditis.

Coagulase-negative staphylococci are proficient biofilm producers. Consequently, débridement and removal of the infected prosthetic device or foreign body are paramount. Prosthetic joint infections occurring more than 1 month after device implantation are best managed with removal of the prosthesis and reimplantation in a one-stage or two-stage procedure. Antimicrobial therapy for these infections is similar to that for *S. aureus*, except that hematogenous seeding rarely occurs, so attention is focused primarily on source control.

Coagulase-negative staphylococci, because they are normal skin flora, are common blood culture contaminants. Approximately 75% of cases in which a blood culture is positive for coagulase-negative staphylococci reflect contamination rather than infection. Sorting out whether a positive culture represents contamination or true infection can be challenging. A single positive blood culture or blood cultures in which more than one strain is present are likely to be due to contamination. Time to blood culture positivity, quantitative blood cultures, and the presence of multiple positive cultures can be useful in determining whether a positive blood culture represents true infection. Isolation of coagulase-negative staphylococci from the blood of a patient with a prosthetic valve, intravenous pacemaker, or vascular graft can be especially problematic because these patients are at high risk for true infection. Unless the patient is hemodynamically unstable or otherwise seriously ill, it is advisable to withhold antibiotics until additional culture specimens are obtained to document the presence of true bacteremia. Isolation of coagulase-negative staphylococci from culture specimens of deep tissue, bone, prosthetic devices, or other normally sterile sites, especially if multiple cultures are positive, strongly suggests true infection.

Staphylococcus lugdunensis causes infections that clinically resemble *S. aureus* infections and can occur in the absence of a foreign body and in otherwise normal hosts. These include prosthetic valve and native valve endocarditis, bacteremia, skin and soft tissue infection, septic arthritis, prosthetic joint infection, and osteomyelitis. *S. lugdunensis* is susceptible to most antibiotics, including penicillin (approximately 75% of isolates), and methicillin resistance is rare. Management of these infections is similar to that of *S. aureus* infections.

STREPTOCOCCUS PNEUMONIAE PULMONARY INFECTIONS

THOMAS MCDONALD FILE, JR.

DEFINITION

Streptococcus pneumoniae (*S. pneumoniae*) is a significant human bacterial pathogen and a major cause of community-associated bacterial infections. It is the most common bacterial cause of community acquired pneumonia (pneumococcal pneumonia; Chapter 85), sinusitis (Chapter 394), and bacterial meningitis (Chapter 381). Despite the availability of an effective vaccine, the burden of pneumococcal pneumonia remains high, particularly in older adults and in patients with underlying comorbid conditions.[1]

The Pathogen

S. pneumoniae (pneumococci) are lancet-shaped, encapsulated, gram-positive cocci. The cells are 0.5 to 1.2 µm in size and usually arranged end to end in pairs—often referred to as diplococci (Fig. 268-1). Colonies appear α-hemolytic, demonstrate fastidious growth, and require catalase (e.g., blood) to grow on agar plates. The major virulence factor is a polysaccharide capsule that covers the organism and inhibits phagocytosis. Strains of pneumococci are classified according to the type of capsule, of which there are 100 known serotypes. Most *S. pneumoniae* serotypes have been shown to cause disease, but only a minority of serotypes produce the majority of pneumococcal infections.

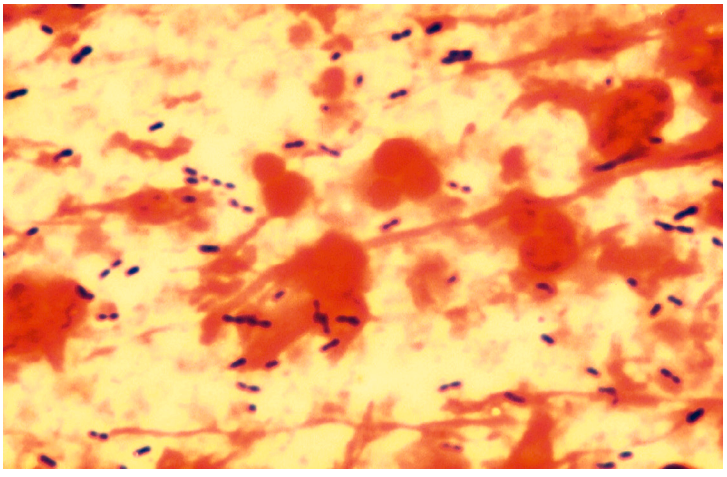

FIGURE 268-1. Gram stain of sputum from patient with pneumococcal pneumonia showing gram-positive diplococci aligned end to end.

However, serotype patterns are slowly changing, in part because of the widespread use of polyvalent vaccine. Strains of *S. pneumoniae* can occasionally change capsular type via exchanging genes between different serotypes involved in capsule synthesis. In addition, genetic mutations or deletions can result in emergence of nonencapsulated strains. Such strains are less virulent but can be associated with noninvasive infection (e.g., conjunctivitis or otitis) and less commonly pneumonia. Another significant virulence factor, pneumolysin, is a cytolysin that causes damage to host cells and interferes with host immunity.

EPIDEMIOLOGY

Each year in the United States, pneumococcal disease accounts for a substantial number of cases of invasive and noninvasive disease. Invasive pneumococcal disease includes cases with isolation of *S. pneumoniae* from normally sterile sites (e.g., blood, cerebrospinal fluid).

S. pneumoniae is the leading cause of mortality due to lower respiratory tract infections globally and causes approximately 1.2 million deaths each year.[2] In 2020, the rate of invasive pneumococcal disease (mostly due to bacterial pneumonia) in the United States was 9.6/100,000 population, with a death rate of 1.06/100,000,[3] and these rates are similar in Europe.[4] The incidence of pneumococcal pneumonia declined by about 30% in industrialized countries during the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) pandemic.[5]

The widespread use of pneumococcal vaccines, especially the pneumococcal conjugate vaccine (PCV13), has reduced the incidence of pneumococcal infections, but the emergence of non-PCV13 serotypes[6] has resulted in an increase back to or close to prevaccine levels.[7] Furthermore, the number of cases is expected to increase as the population of elderly individuals increases.

S. pneumoniae, which remains the most common cause of community-acquired pneumonia (Chapter 85), is isolated by culture in only 5 to 15% of cases in the United States, but quantitative molecular data indicate that the true rate is probably about 30%. Pneumococcal pneumonia is associated with bacteremia in approximately 10 to 30% of cases.

About 5 to 10% of patients with pneumococcal pneumonia will die, and the death rate is higher in patients requiring hospitalization or who are age 65 years and older. Fewer patients will develop pneumococcal meningitis (Chapter 381), but the mortality rate for this infection is much higher.

Risk factors for pneumococcal pneumonia include smoking (Chapter 363); asthma (Chapter 75); alcohol use disorder (Chapter 364); underlying chronic lung (Chapters 76, 78, and 80) or heart disease (Chapter 46); diabetes (Chapter 210); cirrhosis (Chapter 139); renal insufficiency (Chapter 116); dementia (Chapter 371); malnutrition (Chapter 198); sickle cell anemia (Chapter 149); immunocompromise, including HIV infection (Chapter 358); intravenous drug use (Chapter 365); and homelessness.[8] Prior or co-infection with a respiratory virus, especially influenza (Chapter 332), is also a risk factor for *S. pneumoniae*.[9] SARS-CoV-2 infection (Chapter 336) can similarly reduce host defenses of the respiratory tract against *S. pneumoniae*.[10,11]

PATHOBIOLOGY

S. pneumoniae is an exclusively human pathogen and is predominantly spread from direct person-to-person contact via airborne droplets. The spread of

STREPTOCOCCUS PNEUMONIAE PULMONARY INFECTIONS

THOMAS MCDONALD FILE, JR.

DEFINITION

Streptococcus pneumoniae (*S. pneumoniae*) is a significant human bacterial pathogen and a major cause of community-associated bacterial infections. It is the most common bacterial cause of community acquired pneumonia (pneumococcal pneumonia; Chapter 85), sinusitis (Chapter 394), and bacterial meningitis (Chapter 381). Despite the availability of an effective vaccine, the burden of pneumococcal pneumonia remains high, particularly in older adults and in patients with underlying comorbid conditions.[1]

The Pathogen

S. pneumoniae (pneumococci) are lancet-shaped, encapsulated, gram-positive cocci. The cells are 0.5 to 1.2 µm in size and usually arranged end to end in pairs—often referred to as diplococci (Fig. 268-1). Colonies appear α-hemolytic, demonstrate fastidious growth, and require catalase (e.g., blood) to grow on agar plates. The major virulence factor is a polysaccharide capsule that covers the organism and inhibits phagocytosis. Strains of pneumococci are classified according to the type of capsule, of which there are 100 known serotypes. Most *S. pneumoniae* serotypes have been shown to cause disease, but only a minority of serotypes produce the majority of pneumococcal infections.

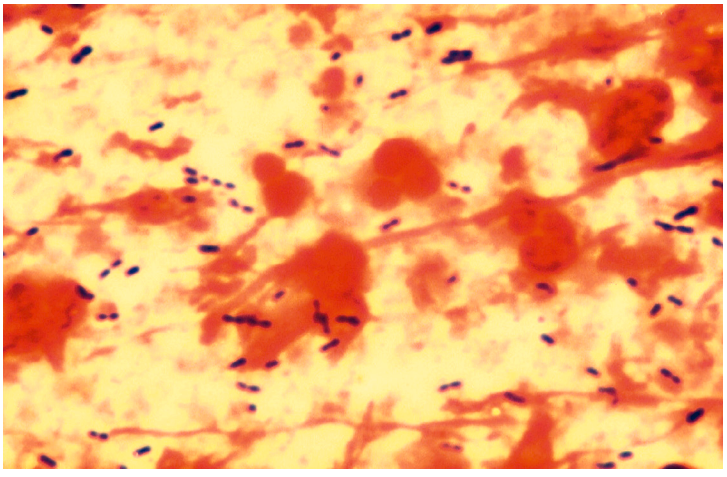

FIGURE 268-1. Gram stain of sputum from patient with pneumococcal pneumonia showing gram-positive diplococci aligned end to end.

However, serotype patterns are slowly changing, in part because of the widespread use of polyvalent vaccine. Strains of *S. pneumoniae* can occasionally change capsular type via exchanging genes between different serotypes involved in capsule synthesis. In addition, genetic mutations or deletions can result in emergence of nonencapsulated strains. Such strains are less virulent but can be associated with noninvasive infection (e.g., conjunctivitis or otitis) and less commonly pneumonia. Another significant virulence factor, pneumolysin, is a cytolysin that causes damage to host cells and interferes with host immunity.

EPIDEMIOLOGY

Each year in the United States, pneumococcal disease accounts for a substantial number of cases of invasive and noninvasive disease. Invasive pneumococcal disease includes cases with isolation of *S. pneumoniae* from normally sterile sites (e.g., blood, cerebrospinal fluid).

S. pneumoniae is the leading cause of mortality due to lower respiratory tract infections globally and causes approximately 1.2 million deaths each year.[2] In 2020, the rate of invasive pneumococcal disease (mostly due to bacterial pneumonia) in the United States was 9.6/100,000 population, with a death rate of 1.06/100,000,[3] and these rates are similar in Europe.[4] The incidence of pneumococcal pneumonia declined by about 30% in industrialized countries during the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) pandemic.[5]

The widespread use of pneumococcal vaccines, especially the pneumococcal conjugate vaccine (PCV13), has reduced the incidence of pneumococcal infections, but the emergence of non-PCV13 serotypes[6] has resulted in an increase back to or close to prevaccine levels.[7] Furthermore, the number of cases is expected to increase as the population of elderly individuals increases.

S. pneumoniae, which remains the most common cause of community-acquired pneumonia (Chapter 85), is isolated by culture in only 5 to 15% of cases in the United States, but quantitative molecular data indicate that the true rate is probably about 30%. Pneumococcal pneumonia is associated with bacteremia in approximately 10 to 30% of cases.

About 5 to 10% of patients with pneumococcal pneumonia will die, and the death rate is higher in patients requiring hospitalization or who are age 65 years and older. Fewer patients will develop pneumococcal meningitis (Chapter 381), but the mortality rate for this infection is much higher.

Risk factors for pneumococcal pneumonia include smoking (Chapter 363); asthma (Chapter 75); alcohol use disorder (Chapter 364); underlying chronic lung (Chapters 76, 78, and 80) or heart disease (Chapter 46); diabetes (Chapter 210); cirrhosis (Chapter 139); renal insufficiency (Chapter 116); dementia (Chapter 371); malnutrition (Chapter 198); sickle cell anemia (Chapter 149); immunocompromise, including HIV infection (Chapter 358); intravenous drug use (Chapter 365); and homelessness.[8] Prior or co-infection with a respiratory virus, especially influenza (Chapter 332), is also a risk factor for *S. pneumoniae*.[9] SARS-CoV-2 infection (Chapter 336) can similarly reduce host defenses of the respiratory tract against *S. pneumoniae*.[10,11]

PATHOBIOLOGY

S. pneumoniae is an exclusively human pathogen and is predominantly spread from direct person-to-person contact via airborne droplets. The spread of

ABSTRACT

Streptococcus pneumoniae (*S. pneumoniae*) is the most common bacterial cause of community-acquired pneumonia. Despite the availability of an effective vaccine, the burden of pneumococcal pneumonia is high, particularly in older adults and in patients who have underlying comorbid conditions. Risk factors for pneumococcal pneumonia include prior viral infections, underlying conditions, and immune deficiency. Pneumococcal pneumonia may be mild, but the wide range of severity includes overwhelming sepsis, in which the mortality rate may be greater than 50%. Potential complications include bacteremia with metastatic infection (e.g., septic arthritis, peritonitis, pericarditis, meningitis, endocarditis) and pulmonary complications (e.g., parapneumonic effusion, empyema, necrotizing pneumonia, lung abscess). Up to one third of patients hospitalized with pneumococcal pneumonia experience major cardiovascular events. Diagnostic tests for pneumonia caused by *S. pneumoniae* include sputum Gram stain and culture, blood culture, immunochromatography, and molecular methods. The majority of patients with community-acquired pneumonia are treated empirically with a regimen that is likely to have activity against *S. pneumoniae*. The choice of initial therapy is complicated by the emergence of antibiotic resistance among *S. pneumoniae*. The best way to prevent pneumococcal pneumonia is through vaccination and stabilization of underlying conditions that predispose to infection (e.g., diabetes, heart failure).

the organism is influenced by such factors as crowding, especially during the winter and in early spring when respiratory diseases are more prevalent. After transmission, the organism commonly colonizes the nasopharynx, from which it can spread to the lungs, paranasal sinuses, or middle ear.[12] It can also be transported in the blood to distal sites such as the brain, heart, and joints. Colonization in the pharynx is mediated by the binding of the bacteria to epithelial cells by means of surface protein adhesins. Strains with a smaller capsular size have increased exposure of adhesins, which correlates with enhanced colonization. Pneumococci may be isolated from the nasopharynx of 5 to 50% of healthy persons, depending on the population and setting, and carriage is most common in winter and early spring, especially in school-aged children.

From the nasopharynx, pneumococci can migrate to the lower respiratory tract by microaspiration of oropharyngeal secretions containing the organism. Hematogenous spread from a distant infected site, direct spread from a contiguous focus, and macroaspiration are other mechanisms whereby *S. pneumoniae* may gain access to the lung.

The disease manifestations of *S. pneumoniae* are caused primarily by the host response to infection rather than the production of organism-associated toxins. The development of pneumococcal pneumonia becomes more likely when a more virulent strain or the amount of aspirated pneumococci overwhelms the host defense system in the respiratory tract (Fig. 268-2). Innate host defenses, which reduce development of pneumonia, include the physiologic removal of bacteria, which become enveloped within mucus and eliminated by the action of ciliated epithelial cells of the respiratory tract. Secretory IgA facilitates the trapping of bacteria in mucus by binding bacteria to mucin; secretory IgA protease produced by *S. pneumoniae* can overcome this host defense. In addition, the polysaccharide capsule plays a role in reducing attachment to airway mucus.

S. pneumoniae resists phagocytosis in part because of the antiphagocytic protection by its capsule. Antibodies directed against the specific type of capsular polysaccharide protect against disease caused by that specific strain by facilitating phagocytosis of the organism and killing of the bacteria. Patients with abnormalities related to antibody production (e.g., asplenia, immunoglobulin deficiencies, multiple myeloma, chronic lymphocytic leukemia) or to phagocytic function (e.g., chronic granulomatous disease, hyperimmunoglobulin E syndrome, myeloperoxidase deficiency, Chediak-Higashi syndrome) are at higher risk for pneumococcal pneumonia and for worse outcomes when infection occurs.

CLINICAL MANIFESTATIONS

The onset of clinical manifestations of pneumococcal pneumonia can be mild, but the wide range of severity includes patients with overwhelming sepsis in whom the mortality rate may be greater than 50%. Classically, the onset is abrupt with fever, chills (often shaking), cough, and pain (often pleuritic). However, this constellation of manifestations presents in only a minority of cases, and the presenting manifestations overlap with those associated with other causes of pneumonia (Chapter 85). Most patients with pneumonia have tachycardia and tachypnea. Older patients may present with delirium as an initial manifestation. Other symptoms include vomiting, diarrhea, myalgias, and arthralgias. Severe infection may be associated with multiple organ dysfunction.

Auscultatory findings of crackling rales and bronchial breath sounds are localized to the involved segment or lobe. Confusion, obtundation, and stiff neck should lead to consideration of meningitis. Hypoxia by pulse oximetry is common.

The classic description of the sputum in lobar pneumococcal pneumonia is "rusty," owing to mixed blood cells and hemoglobin in the sputum. Laboratory abnormalities include leukocytosis with left shift. Leukopenia is found in a minority of cases and is associated with a poor prognosis.

Chest radiography typically reveals a homogenous lobar or segmental alveolar infiltrate, often with a small amount of pleural fluid, but pneumococcal pneumonia also can cause a bronchopneumonia characterized by multiple opacities that tend to be patchy and/or confluent. Chest computed tomography may demonstrate additional complications including abscess, pleural effusions, or lymphadenopathy. Lung ultrasound can demonstrate subpleural consolidation, fluid-filled airspaces, irregular interfaces between consolidated and aerated areas of the lung, and hepatization, in which the lung develops a relatively fine echotexture similar to the liver.

Complications

Potential complications of pneumococcal pneumonia include bacteremia with metastatic infection (septic arthritis, peritonitis, pericarditis, meningitis,[13] endocarditis[14]) and pulmonary complications of parapneumonic effusion, empyema, necrotizing pneumonia, and lung abscess. Risk factors for a complicated course include older age, preexisting lung disease, immunodeficiency or AIDS, and, importantly, acquisition of another nosocomial infection. The risk of overwhelming pneumococcal sepsis is increased in splenectomized patients, because the spleen is a principal site for clearance of this bacterium.

Up to one third of patients hospitalized with pneumococcal pneumonia experience major cardiovascular events. In addition to the stress, hypoxemia, and inflammation associated with infection, pneumolysin may play a direct role in injury to the myocardium. Direct infection of cardiac muscle may be an additional mechanism.

Other Pneumococcal Infections

Pneumococcal species can cause meningitis (Chapter 381), endocarditis (Chapter 61), empyema (Chapter 86), sinusitis (Chapter 394), and otitis (Chapter 394). These infections are described in their respective chapters.

DIAGNOSIS

The cause of community-acquired pneumonia, based on standard diagnostic methods, is identified in a minority of cases (Table 85-1).[15] Diagnostic tests for pneumonia caused by *S. pneumoniae* include molecular methods, sputum Gram stain and culture, blood culture, and immunochromatography. Nucleic acid amplification techniques, which can detect multiple respiratory pathogens including bacteria and viruses from a single respiratory tract sample,[16] are increasingly the standard of care for community-acquired pneumonia (Chapter 85).

The etiologic role of *S. pneumoniae* can be strongly implicated by the presence of gram-positive lancet-shaped diplococci on sputum Gram stain (Fig. 268-1) and isolation by culture. Sputum culture is recommended in patients who have severe community-acquired pneumonia, especially if they are intubated, are being empirically treated for *S. aureus* (Chapter 267) or *P. aeruginosa* (Chapter 282), or have received parenteral antibiotics within the past 90 days, so that its results can potentially narrow antibiotic therapy. However, *S. pneumoniae* is recovered in a minority of sputum cultures in part because the organism has fastidious nutritional requirements and is often overgrown by contaminating oral bacteria. To be reliable, the specimen should be actual sputum and not saliva, with microscopy showing high numbers of polymorphonuclear cells and few epithelial cells.

The yield of blood cultures for patients admitted with community-acquired pneumonia is only 5 to 15%, depending on the severity of disease, with *S. pneumoniae* accounting for approximately two-thirds of the positive results. Guidelines recommend blood cultures for patients who require admission to an intensive care unit or who meet criteria for sputum culture because they may be the only documentation of pneumococcal infection.[17] Urinary antigen tests can detect pneumococcal pneumonia when cultures cannot be obtained in a timely fashion or when antibiotic therapy has already been initiated, with a sensitivity of 50 to 80% and a specificity exceeding 90%.[18]

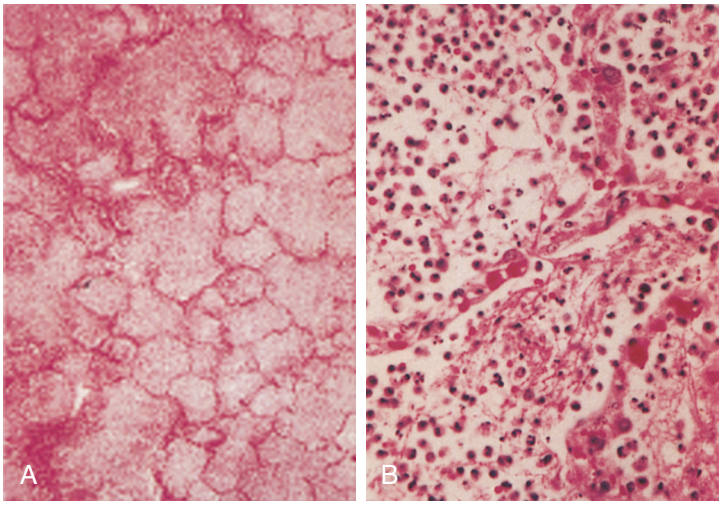

FIGURE 268-2. Pneumonia. A, Low-power magnification (×100) of hematoxylin and eosin (H&E) stain of tissue section from the left lower lobe of the lung. Note the intact alveolar walls and alveoli filled with edema and thick cellular exudates. **B,** Higher magnification (×500) H&E stain of the same section shown in A. Note the heavy infiltrate of polymorphonuclear cells and the intact alveolar walls.

TREATMENT

Choosing Antibiotic Therapy

Antibiotic therapy for community-acquired pneumonia should be begun as soon as possible on an empiric basis because the causative organism is not identified in an appreciable proportion of patients (Chapter 85).[19] Antibiotics (Table 268-1) should be started. The initial regimen should have activity against *S. pneumoniae*, then the regimen should be narrowed to just *S. pneumoniae* (E-Table 268-1) when it is documented by molecular methods, Gram stain and sputum culture, blood culture, or pneumococcal urinary antigen.

Oral agents can usually be used for outpatient therapy in many patients with community-acquired pneumonia (see Chapter 85), but many patients with confirmed pneumococcal pneumonia are sick enough to require hospital admission. Hospitalized patients are initially treated with an intravenous regimen until clinical improvement allows transition to oral therapy.

For admitted patients, combination therapy with a β-lactam plus a macrolide or monotherapy with a respiratory fluoroquinolone are generally of comparable efficacy, but the former is usually preferred. Patients who have a history of a mild penicillin reaction can receive a third- or fourth-generation cephalosporin or carbapenem safely. If there is significant concern to warrant avoidance of a cephalosporin or carbapenem, however, an alternative regimen should be given.

Risk factors for drug-resistant *S. pneumoniae* in adults include age greater than 65 years, recent antimicrobial therapy, alcohol use disorder, an immunosuppressive illness or therapy, exposure to a child in a daycare center, recent prior hospitalization, or residence in a long-term care facility. Rates of resistance are above 30% for macrolides, less than 2% to the newer fluoroquinolones (levofloxacin, moxifloxacin) in the United States but higher in some countries, and low to β-lactam drugs (e.g., amoxicillin, ceftriaxone, cefotaxime).[20]

Response to Therapy

With appropriate antibiotic therapy, some improvement in the patient's clinical course is usually seen within 72 to 96 hours. The recommended duration of therapy for patients with a good clinical response within the first 3 days of therapy is generally 5 days total, but 3 days may be adequate in patients who were not admitted to an intensive care unit and who are completely stable clinically.[A1] Before stopping therapy, the patient should be afebrile, breathing without supplemental oxygen (unless required for preexisting disease), and hemodynamically stable. A longer duration is needed for more complicated infections (e.g., empyema, extrapulmonary infection such as meningitis, endocarditis, septic arthritis).

The use of the serum biomarker procalcitonin can help guide duration of antimicrobial therapy. Procalcitonin promptly increases within 6 to 12 hours of the initial infection and decreases rapidly when the bacterial infection is controlled. Antibiotic duration guided by serial measurement of the procalcitonin level can safely reduce duration of treatment in patients with pneumococcal pneumonia.[A2]

Guidelines do not recommend routine use of corticosteroids. However, they may be beneficial for patients who have evidence of severe pneumonia with an exaggerated or dysregulated inflammatory response, defined as a severe inflammatory response, respiratory failure, or septic shock.[A3,A4,A5]

Although a clinical response to appropriate antibiotic therapy is seen relatively quickly, cough may persist for a week or longer, and auscultatory crackles may take 3 weeks to clear. Patients who do not demonstrate some clinical improvement within 72 to 96 hours are considered nonresponders. Most common causes include severe disease, resistant strains, extrapulmonary infection (e.g., empyema, metastatic infection), unstable comorbid conditions, and noninfectious causes (e.g., pulmonary embolism, lung cancer, drug reactions, or immunodeficiency).

TABLE 268-1 ANTIMICROBIAL THERAPY FOR PNEUMOCOCCAL PNEUMONIA

	PREFERRED ANTIMICROBIALS	ALTERNATIVE ANTIMICROBIALS
ORAL AGENTS		
Penicillin susceptible (MIC ≤0.06 μg/mL)*	Amoxicillin; penicillin	Oral cephalosporins (cefpodoxime; cefdinir; cefditoren; cefuroxime) Oral macrolides if susceptible in vitro† Clindamycin; doxycycline; omadacycline¶ Lefamulin¶ Respiratory fluoroquinolones (levofloxacin, moxifloxacin, gemifloxacin)
Penicillin resistant*	Fluoroquinolone; high-dose amoxicillin (3 g/day)	Clindamycin; linezolid; lefamulin¶; omadacycline¶
INTRAVENOUS AGENTS	Third-generation cephalosporin (ceftriaxone, cefotaxime); ceftaroline§; penicillin‡; ampicillin‡	Fluoroquinolones; vancomycin; clindamycin; linezolid; broad-spectrum β-lactams‖; tigecycline; lefamulin¶; omadacycline¶

*Based on nonmeningitis breakpoint for oral penicillin; parenteral penicillin nonmeningitis breakpoint is ≤2.0 μg/mL; if concern for meningitis, breakpoint for susceptible isolates is 0.06 μg/mL.

†High rate of resistance in United States and not recommended for empirical therapy without knowledge of the susceptibility results.

‡High dose (≥18 million units of penicillin or 12 g of ampicillin likely to be effective for most strains with elevated MICs).

§Ceftaroline more potent for *S. pneumoniae* than the third-generation cephalosporin (3rd-gen Ceph) and often active even if resistant to 3rd-gen Ceph.

‖Piperacillin/tazobactam, cefepime, ceftazidime, ertapenem, imipenem, and meropenem.

¶Lefamulin and omadacycline are newer agents that are active against most community-acquired pneumonia pathogens including *S. pneumoniae, H. influenza, M. catarrhalis, S. aureus*, and atypical pathogens; lefamulin lacks activity against Enterobacteriaceae so can be considered as more targeted for the community-acquired pneumonia pathogens, whereas omadacycline has activity against many Enterobacteriaceae and may be more appropriate for patients with structural lung disease.

PROGNOSIS

The mortality rate for pneumococcal pneumonia varies by severity at presentation and host factors, but overall it is as high as 11% in hospitalized patients. Patients with bacteremic pneumococcal pneumonia have higher in-hospital mortality and longer length of hospital stay. Other factors associated with increased mortality include older age, severity of disease, requirement for ventilation, shock, bilateral disease, amount and degree of underlying conditions, and renal failure.

PREVENTION

The best way to prevent pneumococcal infection is by vaccination and stabilization of underlying conditions that predispose to infection (e.g., diabetes, heart failure).

There are two types of pneumococcal vaccine recommended for adults: a pneumococcal conjugate vaccine (i.e., PCV13, PCV 15, and PCV 20) and a pneumococcal polysaccharide vaccine (i.e., PPSV23). The conjugate vaccine contains antigens for 13, 15, or 20 serotypes and is more immunogenic,[A6] whereas the polysaccharide contains antigens of 23 serotypes. Recommendations for pneumococcal vaccine are based on age and underlying conditions (Chapter 15).

Influenza vaccine also reduces pneumococcal pneumonia, because by reducing the morbidity of acute influenza, the incidence of postinfluenza bacterial pneumonia is lessened. Dental hygiene may reduce the infectious consequences of aspiration. The relatively simple act of daily teeth brushing may help prevent pneumococcal pneumonia.

269 NONPNEUMOCOCCAL STREPTOCOCCAL INFECTIONS AND RHEUMATIC FEVER

DENNIS L. STEVENS, AMY E. BRYANT, AND MELISSA M. HAGMAN

CLASSIFICATION AND IDENTIFICATION OF STREPTOCOCCI

Streptococci are gram-positive facultatively anaerobic, catalase-negative coccoid bacteria that grow in chains and colonize the skin and mucous membranes. When grown on blood agar plates, they may cause complete (β), incomplete (α), or no (γ) hemolysis. Using the Lancefield classification, hemolytic streptococci can be classified into types A through G based on acid-extractable carbohydrate antigens of cell wall material. Modern classification schemes categorize hemolytic and nonhemolytic streptococci using complex biochemical and genetic techniques.

The major pathogenic β-hemolytic streptococci are group A *(Streptococcus pyogenes)* and group B *(Streptococcus agalactiae)*. Although most of this chapter is dedicated to discussing these two pathogens and the clinical diseases that they cause, the remainder of the chapter includes discussions of *Streptococcus dysgalactiae* subspecies *equisimilis* (groups C and G streptococcus), viridans group streptococcus (no Lancefield group), and zoonotic streptococci (various Lancefield groups).

STREPTOCOCCUS PYOGENES (GROUP A STREPTOCOCCUS) INFECTIONS

Acute Infections

DEFINITION

S. pyogenes contains Lancefield group A antigen on the cell surface and thus is referred to as group A streptococcus. Group A streptococci are the most significant of the streptococcal human pathogens and cause an array of clinical infections ranging from pharyngitis, superficial skin infections, deep soft tissue infections, and toxic shock syndrome. Postinfectious sequelae include rheumatic fever, post-streptococcal glomerulonephritis, and reactive arthritis.[1]

EPIDEMIOLOGY

Humans are the only known hosts for *S. pyogenes*. All group A streptococcal infections are more common in children younger than age 10 years. The asymptomatic prevalence of the group A streptococcus carrier state is also higher in children (15 to 20%) than in adults (<5%). In addition to age, group A streptococcus epidemics are also associated with crowded conditions, particularly in schools and military camps, during the winter months in temperate climates. The U.S. Centers for Disease Control and Prevention (CDC) estimates that the incidence of invasive *S. pyogenes* infections in the United States in 2019 was 7.5 cases per 100,000 population per year. Worldwide, an estimated 18 million annual infections cause about 500,000 deaths each year.[2]

Pharyngeal and cutaneous group A streptococci are transmitted from person to person by aerosolized microdroplets or direct contact. Epidemics of pharyngitis and scarlet fever occur after the consumption of contaminated food or unpasteurized milk. Group A streptococcus infections are seen in hospitalized patients during childbirth (puerperal sepsis), after surgery or burns (wound infection), and in war settings (epidemic gangrene). Thus, most clinical streptococcal infections have a clear mode of transmission and portal of entry. In contrast, among patients with streptococcal toxic shock syndrome, the portal of entry is obvious in only 50% of cases.

PATHOBIOLOGY

Mucous membranes and skin serve as the natural reservoirs for *S. pyogenes*. Group A streptococci adhere to host epithelium through complex interactions involving streptococcal factors such as M protein, lipoteichoic acid, fibronectin-binding protein, and fimbriae.[3] Although streptococci must adhere to the epithelium to cause most infections, such adherence is not always sufficient to cause disease because many individuals may have prolonged asymptomatic carriage without clinical infection.

Streptococci evade opsonophagocytosis by expression of antiphagocytic M protein, by use of immunoglobulin-binding protein, by formation of a hyaluronic acid capsule, and/or by production of a C5a peptidase that destroys or inactivates complement-derived chemoattractants and opsonins.[4] At the focus of infection, the exotoxin streptolysin O is cytotoxic and destroys approaching phagocytes. Distal to the infection, lower concentrations of streptolysin O stimulate hyperadhesion of polymorphonuclear leukocytes to endothelial cells (thereby effectively preventing a tissue inflammatory response and promoting vascular damage) and cause vascular occlusion with destruction of distal fascia and muscle. In a nonimmune host, streptolysin O, streptococcal pyrogenic exotoxins, and other streptococcal components drive the "cytokine storm" that causes hypotension and vascular leukostasis, thereby resulting in shock, microvascular injury, multiorgan failure, and even death.

M Proteins

More than 150 different M protein serotypes of group A streptococci have been described. The M protein is a coiled-coil structure that consists of four regions of repeating amino acids (A to D), a proline/glycine-rich region that intercalates the protein into the bacterial cell wall, and a hydrophobic membrane anchor. Region A, which is near the *N* terminus, is highly variable, and antibodies to this region confer type-specific protection by overcoming the antiphagocytic properties of the protein. The more conserved B to D regions bind complement regulatory proteins, sterically inhibiting antibody binding and complement-derived opsonin deposition and effectively camouflaging the organism against humoral immune surveillance. The quantity of M protein that is produced by an infecting strain progressively decreases during convalescence and during prolonged asymptomatic carriage.

Cell Wall, Lipoteichoic Acid, Fibronectin-Binding Protein (Protein F), and Fimbriae

Many different factors help group A streptococci adhere to host epithelial cells. Integral lipoteichoic acid components of the cell wall mediate hydrophobic interactions between pathogen and host cells. Fibronectin-binding protein (protein F) promotes binding to the host cell extracellular matrix. Fimbriae, flexible rods that protrude up to 3 μm from the bacterial cell surface, mediate adherence to epithelial cells and promote microcolony and biofilm formation.

Hyaluronic Acid Capsule

Some strains of *S. pyogenes* have hyaluronic acid capsules. These capsules, which bind to CD44 on epithelial cells and serve as antiphagocytic factors, are important in pharyngitis, soft tissue infection, and invasive disease.

Streptolysin O and S

Streptolysin O belongs to a family of highly homologous oxygen-labile, cholesterol-dependent cytolysins. These cytotoxins cause the broad zone of complete β-hemolysis that surrounds colonies of *S. pyogenes* grown on blood agar plates. As the name implies, cholesterol-dependent cytolysins bind to cholesterol on eukaryotic cell membranes, where they create toxin-cholesterol membrane pores that, at high doses, cause cell lysis by a colloid-osmotic mechanism. Sublytic doses stimulate cardiac cell dysfunction, leukocyte granule release, and intravascular leukostasis and blood flow occlusion. Anti-streptolysin O titers are used clinically to detect recent group A streptococcal infection and to aid in diagnosis of post-streptococcal syndromes such acute rheumatic fever and post-streptococcal glomerulonephritis. When the serum cholesterol level is high, as in the nephrotic syndrome, the anti-streptolysin O titer may be falsely elevated.

Streptolysin S is a cell-associated hemolysin that does not diffuse into the agar media. Purification and characterization of this protein have been difficult, and its only pathogenetic role may be in direct or contact cytotoxicity.

Deoxyribonucleases A, B, C, and D

The expression of deoxyribonucleases (DNases), especially the DNase B seen with group A streptococci, stimulates the production of anti-DNase antibody following both pharyngeal and skin infection. DNases may also contribute to the production of cytokines, but their importance in this setting is not essential.

Hyaluronidase and Nicotine Adenine Dinucleotidase

Hyaluronidase is an extracellular enzyme that hydrolyzes hyaluronic acid in deeper tissues, thereby facilitating the spread of infection along fascial planes. Antihyaluronidase titers rise after *S. pyogenes* infection, especially skin infections. The production of nicotine adenine dinucleotidase among group A streptococcus strains correlates with the epidemiologic emergence/reemergence of

ABSTRACT

The major pathogenic β-hemolytic streptococci are group A *(Streptococcus pyogenes)* and group B *(Streptococcus agalactiae)*. *S. pyogenes* causes an array of clinical infections ranging from pharyngitis and superficial skin infections to deep soft tissue infections and toxic shock syndrome. Postinfectious sequelae include rheumatic fever and post-streptococcal glomerulonephritis. Penicillin remains the drug of first choice for treatment of *S. pyogenes* infection. Cephalosporins are a reasonable alternative. Clindamycin should be used in addition to penicillin in serious group A streptococcal infection due to the ability of clindamycin to prevent production of exotoxins that mediate the clinical manifestations of disease. *S. agalactiae* causes infection in neonates, pregnant women, and nonpregnant adults, especially the elderly and those with diabetes and other underlying medical disease. In adults, the most common manifestations of group B streptococcal disease are soft tissue infection, osteomyelitis, and septic arthritis. Treatment is with penicillin. Although most of this chapter is dedicated to discussing group A streptococci, group B streptococci, and the clinical diseases they cause, the remainder of the chapter includes discussions of *Streptococcus dysgalactiae* subspecies *equisimilis* (group C and G streptococcus), viridans group streptococcus (no Lancefield group), and zoonotic streptococci (various Lancefield groups).

necrotizing fasciitis and streptococcal toxic shock syndrome. In neutrophils, nicotine adenine dinucleotidase impairs chemotaxis and changes the respiratory burst activity.

Pyrogenic Exotoxins

Streptococcal pyrogenic exotoxins types A, B, and C are also called scarlatina or erythrogenic toxins. These exotoxins act as superantigens that induce lymphocyte blastogenesis and fever, may potentiate endotoxin-induced shock, and may suppress antibody synthesis. Pyrogenic exotoxins and some M protein fragments are initially able to interact with certain V_β regions of the T-cell receptor despite the absence of classic antigen processing by antigen-presenting cells (E-Fig. 269-1). This interaction results in massive clonal proliferation of T-lymphocytes as well as stimulation of macrophages. Thus, streptococcal toxic shock syndrome causes watershed production of lymphokines (tumor necrosis factor-β [TNF-β], interferon-γ, and interleukin-2 [IL-2]) and monokines (TNF-α, IL-1, and IL-6) that results in the "cytokine storm," which in turn mediates shock and organ dysfunction. Five other group A streptococcal superantigens, including streptococcal superantigen (SSA) and mitogenic factor, may also play a role in the pathogenesis. In addition, streptococcal pyrogenic exotoxins type B, which is a cysteine protease, may contribute to the pathogenesis of necrotizing fasciitis and shock by its ability to cleave pre–IL-1β into active IL-1β.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Pharyngitis

Pharyngitis is the most common *S. pyogenes* infection, with peak incidence in children aged 5 to 15 years. Infection is characterized by an abrupt onset of fever, sore throat, and submandibular adenopathy. Chilliness is common, but frank rigors are unusual. Most patients report pain on swallowing, but cough and hoarseness are rare. On physical examination, the uvula is edematous, the tonsils are typically hypertrophied, the palate may have petechia, and the pharynx is usually erythematous with a punctate or confluent exudate (Fig. 269-1).

Acute pharyngitis induces antibodies against M protein, streptolysin O, DNase, hyaluronidase, and, if present, pyrogenic exotoxins. Even without treatment, the pain, swelling, and fever of acute pharyngitis usually resolve spontaneously in 3 to 6 days. However, depending on the virulence of the infecting strain, pharyngitis also can progress to suppurative head and neck infections, scarlet fever, bacteremia, rheumatic fever, or post-streptococcal glomerulonephritis. Streptococcal toxic shock syndrome is an uncommon sequela of symptomatic pharyngitis.

Although *S. pyogenes* is the most common cause of acute pharyngitis (20 to 40% of pediatric cases and 5 to 15% of adult cases), definitive diagnosis is difficult on purely clinical parameters. Even in older children or adolescents who have all the typical physical findings of streptococcal pharyngitis, the clinical diagnosis is correct in only about 75% of patients. The modified Centor score was designed to assist with diagnosis and to help reduce unnecessary use of antibiotics and streptococcal testing (Tables 269-1 and 397-2). If any one of the classic signs is absent, the likelihood of streptococcal pharyngitis is greatly reduced. Several societies suggest avoiding streptococcal testing and antibiotics if the modified Centor score is 0 or 1. Providers can generally avoid testing in children younger than age 3 years because of low rates of streptococcal infection complications in this age group.

Throat swabs for culture of *S. pyogenes* remain the diagnostic "gold standard." Rapid site-of-care nucleic acid testing (sensitivity 97.5% and specificity 95%) is preferred over antigen tests, which have a sensitivity of only about 85%.[5,6] A popular approach, which is supported by professional guidelines, is to obtain two throat swabs from the posterior pharynx or tonsillar surface. If a rapid streptococcal test is positive on the first swab, the patient should be treated with antibiotics, and the second swab can be discarded. If the rapid test is negative in children and adolescents, the second sample should be sent for culture and treatment should be withheld unless the result is a positive culture. In adults, the second sample usually need not be sent for culture because of the low incidence of group A streptococcal pharyngitis in adults and the low risk for subsequent acute rheumatic fever even if group A streptococcus pharyngitis is present. The delay in antibiotics for confirmed cases of group A streptococcus pharyngitis is reasonable because acute antibiotic treatment has limited effect on improving acute symptoms. Delaying treatment by several days, however, reduces unnecessary antibiotic use while still achieving the goals of preventing rheumatic fever and reducing spread of disease. Antibiotics, regardless of the timing, do not reduce the likelihood of post-streptococcal glomerulonephritis.

Scarlet Fever

Scarlet fever is the syndrome defined as streptococcal infection (most commonly pharyngitis) with fever and a characteristic rash. Ninety percent of cases of scarlet fever occur in children ages 2 to 8 years. Scarlet fever is most common during the winter months in temperate regions. The rash usually begins as small, flat, erythematous macules on the trunk 1 to 2 days after the illness begins. The rash then transforms into minute papules, giving a "sandpaper" feel to the skin as it spreads to the limbs, sparing the palms and soles. The rash can be accentuated in the skin folds and flexure creases as of the elbow (Pastia lines). Other features include flushed cheeks with circumoral pallor and enlargement of the papillae of the tongue (strawberry tongue). As the rash resolves over the course of 6 to 9 days, there is often desquamation beginning at the palms and soles. Since the advent of penicillin treatment, scarlet fever has become uncommon, but recent outbreaks have been reported in several countries.[7–9]

Impetigo and Ecthyma

Impetigo (Chapter 408) most commonly occurs in children ages 2 to 5 years. It may occur year-round in tropical areas but occurs predominantly in the summer in temperate climates. Risk factors for impetigo include poor hygiene and malnutrition. Unbroken skin is colonized, and then minor abrasions or other traumas lead to infection of the superficial keratin layer of the skin. Within 10 to 14 days,

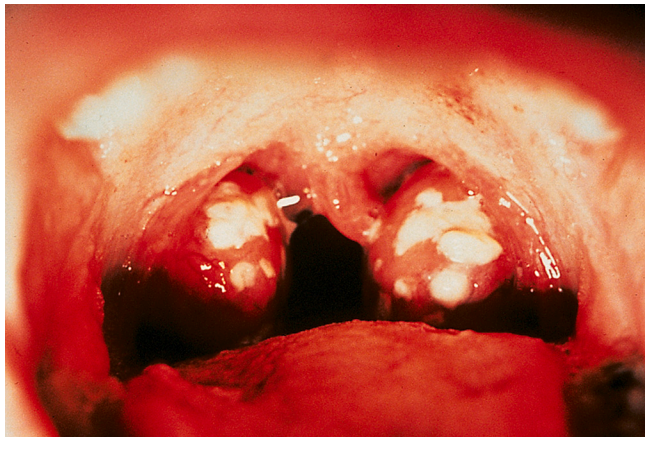

FIGURE 269-1. Acute streptococcal pharyngitis. Pus is present in the tonsillar crypts, and some palatal petechiae are seen. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)

TABLE 269-1 MODIFIED CENTOR CLINICAL DECISION RULE FOR DIAGNOSING GROUP A STREPTOCOCCAL PHARYNGITIS IN CHILDREN AND ADULTS

STEP 1—CALCULATE MODIFIED CENTOR SCORE	
DIAGNOSTIC CRITERIA	**POINTS**
Temperature >38° C	+1
Absence of cough	+1
Swollen, tender anterior cervical lymph nodes	+1
Tonsillar swelling or exudate	+1
Age 3-14 years	+1
Age >44 years	−1

STEP 2—DETERMINE SUGGESTED MANAGEMENT			
SCORE	**RISK FOR STREPTOCOCCAL INFECTION**	**RAPID ANTIGEN TESTING AND/OR CULTURE**	**ANTIBIOTICS**
≤0	1-2.5%	No	No
1	5-10%		
2	11-17%	Yes	If testing positive
3	28-35%		
≥4	51-53%	No	Yes, empirical

E-FIGURE 269-1. Superantigen-induced production of tumor necrosis factor-α (TNF-α) and lymphotoxin (TNF-β) by peripheral blood mononuclear cells. A, Superantigens induce human monocytes to produce TNF-α; however, it is unclear whether such production results solely from direct stimulation of the monocyte by the superantigen. **B**, In mixed mononuclear cell populations, superantigens stimulate TNF-α synthesis in monocytes and, by binding to specific V_β regions of the T-cell receptor, induce the synthesis of TNF-β from T-cells. **C**, The T-cell response to superantigen stimulation includes the production of interleukin-2 (IL-2), which results in clonal proliferation with concordant production of interferon-γ (IFN-γ) and TNF-β. IFN-γ can then amplify monocyte synthesis of TNF-α, IL-1, and IL-6. (From Stevens DL, Bryant AE, Hackett SP. Sepsis syndromes and toxic shock syndromes: concepts in pathogenesis and a perspective of future strategy. *Current Opin Infect Dis*. 1993;6[3]:374-383.)

single or multiple thick-crusted, golden-yellow lesions appear. Ecthyma is an ulcerative form of impetigo characterized by erosions into the dermis. In the past, nonbullous impetigo as described here could be confidently diagnosed as streptococcal and differentiated from bullous impetigo caused by *Staphylococcus aureus* (Chapter 268). More recently, however, *S. aureus* has been isolated with increasing frequency from nonbullous impetigo when treatment with penicillin fails to cure the infection. Gram stain and culture of exudates from the skin lesions can help determine whether group A streptococcus or *S. aureus* is the cause.

Erysipelas

Erysipelas (Chapter 408), which is caused exclusively by *S. pyogenes,* is characterized by an abrupt onset of fiery red swelling of the face or extremities. The infection is most commonly seen in infants and elderly adults. Infection is confined to the upper dermis with prominent lymphatic involvement leading to well-defined margins raised above the level of the surrounding skin, particularly along the nasolabial fold, without the crusty lesions seen in impetigo with its involvement of the superficial keratin layer of skin. Other distinctive features of erysipelas include scarlet or salmon-red rash, intense pain, and rapid progression. Flaccid bullae may develop on the second to third day, but the infection rarely extends into deeper soft tissues.

Cellulitis

Cellulitis (Chapter 408) is infection of the subcutaneous tissues resulting in a pink hue to the skin and less defined borders than with erysipelas. Group A streptococcal cellulitis is usually nonpurulent. Purulent cellulitis is most commonly caused by staphylococcal species. Risk factors for streptococcal cellulitis include impaired lymphatic drainage, venous insufficiency, edema, obesity, and disruption of the cutaneous barrier as from wounds or dermatophyte infection (e.g., tinea pedis).

Severe Group A Streptococcal Infections

Bacteremia

Group A streptococcal bacteremia is relatively uncommon in the antibiotic era, and endocarditis is even less common. In contrast to pharyngitis, scarlet fever, and impetigo, bacteremia occurs more often in the elderly and in neonates. The exceptions to these extremes of age are individuals with parenteral injection of illicit drugs and otherwise healthy middle-aged adults who develop bacteremia as part of a necrotizing soft tissue infection or streptococcal toxic shock syndrome.

Puerperal Sepsis

Patients with *S. pyogenes* puerperal sepsis typically present with fever, abdominal pain, and hypotension without tachycardia or leukocytosis. Maternal mortality is highest when infection occurs within 4 days of delivery or during the late third trimester. The incidence varies from about 6 to 80 cases per 100,000 live births, and the case-fatality rate is about 3.5%. Women who undergo cesarean section (and routinely receive prophylactic antibiotics) or are primiparous are at lower risk. Nosocomial transmission can occur, but because women are discharged home after 48 hours, acquisition may be from the home environment, particularly if young children at home have had recent streptococcal pharyngitis or are carriers of group A streptococcus.

Necrotizing Fasciitis

Necrotizing fasciitis is an infection of the deep subcutaneous tissues and fascia that is characterized by extensive and rapidly spreading necrosis (gangrene) of the skin and underlying structures.[10] Streptococcal necrotizing fasciitis can begin at a site of trivial trauma (e.g., a burn, insect bite, or varicella lesion) or in an operative incision. Half of patients with necrotizing fasciitis, however, develop infection without a defined portal of entry. In these individuals, the "cryptic" infection begins in deep tissues at a site of muscle strain, bruise, or other nonpenetrating traumatic injury. In patients who have necrotizing fasciitis with a portal of entry, warmth, erythema, swelling, and tenderness develop and then rapidly spread both proximally and distally within 24 hours. During the next 24 to 48 hours, the erythema typically turns from red to purple and then to blue, and the patient develops blisters and bullae that contain clear yellow fluid. Bacteremia is frequently present, and metastatic abscesses may occur. By the fourth to fifth day, frank gangrenous changes are evident in the affected skin, followed by extensive sloughing. The process may march inexorably over large body areas unless measures are taken to contain it. The patient with streptococcal necrotizing fasciitis appears perilously ill, with high fever and extreme prostration.

In patients with cryptic *S. pyogenes* necrotizing fasciitis/myonecrosis who lack a discernible portal of bacterial entry, classic cutaneous signs of a necrotizing process are not initially apparent. In the absence of such clinical clues, the correct diagnosis is often missed or delayed until the patient manifests systemic shock and organ failure. Pain out of proportion to the initial injury is usually an important clinical clue to the presence of the deep infection. Routine radiographs, computed tomography (CT) scanning, and magnetic resonance imaging (MRI) may show localized swelling of the deep tissues but characteristically do not show frank abscess or gas formation. Therefore, these are not definitive procedures. Unexplained tachycardia, a marked left shift, and an elevated creatine phosphokinase level can be important clues to the diagnosis of necrotizing soft tissue infections, and their presence should prompt surgical inspection of the deep tissues. Gram stains of aspirated fluid reveal chains of gram-positive cocci and few, if any, white blood cells. Similarly, a biopsy with frozen section may aid in the diagnosis of necrotizing fasciitis.

Myonecrosis

Myonecrosis is an invasive and destructive infection of the muscle and related structures. Among gram-positive organisms, *S. pyogenes* remains the most common etiologic agent. This is in contrast to myositis, which is strictly defined as a localized purulent infection of the muscle, where *S. pyogenes* is rarely involved. In myonecrosis, organisms are likely hematogenously translocated from the throat to the deep soft tissues, though antecedent or concomitant streptococcal pharyngitis is not a prerequisite for this infection.

Streptococcal Toxic Shock Syndrome

Streptococcal toxic shock syndrome (Table 269-2) is any streptococcal infection that is associated with the sudden onset of shock and organ failure.[11] Definite cases are those in which *S. pyogenes* is isolated from a normally sterile body site. Diabetes mellitus and alcohol use disorders appear to be contributing factors, but many afflicted individuals have no underlying medical conditions and are not immunocompromised. This contrasts sharply with reviews of *S. pyogenes* bacteremia from several decades ago, which found that bacteremia occurred primarily in the very young, the very old, or patients with predisposing conditions, such as cancer, renal failure, severe burns, or iatrogenic immunosuppression. Streptococcal toxic shock syndrome rarely occurs secondary to symptomatic streptococcal pharyngitis and more often follows breaches in the skin and mucous membranes. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) for pain associated with muscle strain, trauma, chickenpox, or childbirth may predispose patients to increased risk and severity of infection, perhaps by masking early signs and symptoms and thereby delaying diagnosis and treatment.

The first phase of streptococcal toxic shock syndrome begins with an influenza-like prodrome characterized by fever, chills, myalgias, nausea, vomiting, and diarrhea. Hypotension follows within 24 to 48 hours. Confusion develops in more than half of patients. Phase 2 is characterized by tachycardia, tachypnea, increasing pain, and persistent fevers. In children with varicella infection, toxicity or persistence of fever longer than 4 days should prompt

TABLE 269-2 DEFINITION OF STREPTOCOCCAL TOXIC SHOCK SYNDROME

A. DEFINITION	
Definite case	Illness fulfilling criteria B1 and C (1 and 2)
Probable case	Illness fulfilling criteria B2 and C (1 and 2) if no other cause for illness is found
B. ISOLATION OF GROUP A STREPTOCOCCI	
1. From a normally sterile site (e.g., blood; cerebrospinal, pleural, or peritoneal fluid; tissue biopsy; surgical wound)	
2. From a nonsterile site (e.g., throat, sputum, vagina, superficial skin lesion)	
C. CLINICAL SIGNS OF SEVERE INFECTION	
1. Hypotension (e.g., systolic blood pressure ≤90 mm Hg in adults or below fifth percentile for age in children)	
2. Two or more of the following signs:	
Renal impairment (i.e., creatinine ≥2 mg/dL for adults, or ≥2 times the upper limit of normal for age, or ≥2 times baseline creatinine in persons with preexisting renal disease)	
Coagulopathy (i.e., platelets ≤100,000/μL or disseminated intravascular coagulation)	
Liver involvement (i.e., serum aspartate aminotransferase [AST], alanine aminotransferase [ALT], or total bilirubin levels ≥2 times the upper limit of normal for age, or ≥2 times baseline in persons with preexisting liver disease)	
Acute respiratory distress syndrome	
Generalized erythematous macular rash that may desquamate	
Soft tissue necrosis (e.g., necrotizing fasciitis, myositis, or gangrene)	

Adapted from The Working Group on Severe Streptococcal Infections. Defining the group A streptococcal toxic shock syndrome. Rationale and consensus definition. *JAMA.* 1993;269(3):390-391.

careful evaluation for streptococcal toxic shock syndrome. In phase 3, shock and organ failure develop. Laboratory tests may show evidence of renal impairment and normal to mild elevations of white blood cell count with profound left shift, low albumin, and low calcium. Metabolic acidosis develops in phase 3 of disease. Because acute respiratory distress syndrome (ARDS) develops in 55% of patients with streptococcal toxic shock syndrome, blood gas levels can be helpful to evaluate the need for mechanical ventilation.

Pneumonia

Pneumonia caused by *S. pyogenes* is frequently associated with chronic pulmonary disease or with antecedent viral infections such as influenza, measles, or varicella. In one third or fewer of the cases, patients have a history of preceding streptococcal upper respiratory infection. The onset is typically abrupt, and the disease is characterized by fever, chills, dyspnea, cough productive of blood-streaked sputum, and pleuritic chest pain. The pulmonary picture is one of bronchopneumonia, with consolidation being uncommon. Empyema (Chapter 86) develops in 30 to 40% of cases, tends to appear early in the disease, and typically consists of copious amounts of thin serosanguinous fluid. Bacteremia occurs in 10 to 15% of cases.

TREATMENT AND PROGNOSIS

Antimicrobial Susceptibility

Group A streptococci continue to be susceptible to penicillin, which remains the drug of first choice for treatment of infection. Cephalosporins are a reasonable alternative to penicillin in some cases because of ease of administration. Clindamycin should be used in addition to penicillin in serious group A streptococcal infection owing to the ability of clindamycin to prevent production of group A streptococcus exotoxins that mediate the clinical manifestations of disease. Treatment failures in patients with severe *S. pyogenes* infections have been described if clindamycin resistance is found. In the United States, clindamycin resistance is as high as 15%. In other nations, resistance may be much higher. In China, for example, 95.5% of the strains of group A streptococci causing scarlet fever are clindamycin resistant.

In penicillin-hypersensitive patients, clindamycin or macrolides are the second-line drugs of choice. As with clindamycin, macrolide resistance is increasing. Fluoroquinolones can be used as an alternative for group A streptococcal skin and soft tissue infections in penicillin-hypersensitive patients in areas where clindamycin and macrolide resistance are high. Fluoroquinolone resistance is rare. Vancomycin is an option for intravenous therapy. Linezolid and tedizolid are newer options, especially for deep tissue infection. Tetracycline resistance in group A streptococci is common, and therefore it should not be used unless sensitivities are known. Trimethoprim-sulfamethoxazole is not active against group A streptococci and therefore should not be used alone for infections in which group A streptococcus is the suspected pathogen. However, trimethoprim-sulfamethoxazole (four single-strength pills, each containing 80 mg of trimethoprim and 400 mg of sulfamethoxazole, twice daily for 7 days)[A1] is effective for uncomplicated abscesses in which *Staphylococcus aureus* is thought to be the primary pathogen and *S. pyogenes* only a potential co-pathogen.

Specific Infections

Pharyngitis

The acute symptoms of streptococcal pharyngitis usually resolve within 3 to 6 days even without treatment. The goal of treatment is to reduce the incidence of streptococcal sequelae such as suppurative head and neck infections, scarlet fever, bacteremia, and rheumatic fever.

For pharyngitis in patients over age 6 years, oral penicillin VK (1000 mg three times daily for 10 days or 800 mg four times daily for 5 days)[A2] or injectable benzathine penicillin (1.2 million units intramuscularly once) is the treatment of choice because it is cost effective, has a narrow spectrum of activity, and has long-standing proven efficacy (Chapter 397).[A3] Cephalexin (500 mg orally twice a day for 5 to 10 days) is also effective for primary treatment and for persistent infection. Patients with proven recurrent infections should receive clindamycin (300 mg orally three times a day for 10 days) or amoxicillin–clavulanic acid (875 mg orally twice a day, or 500 mg three times a day for 10 days). For patients who are allergic to penicillin, azithromycin (500 mg orally on the first day and then 250 mg daily for 4 more days) is another alternative.

Scarlet Fever

For scarlet fever, the recommended treatment is 1.2 million units of benzathine penicillin G given intramuscularly or oral penicillin VK, 500 mg four times daily for 10 days. Most patients recover after 4 to 5 days, and the rash usually resolves completely over a period of several weeks.

Skin Infections

Impetigo and Ecthyma

For impetigo and ecthyma, topical agents (e.g., mupirocin 2% ointment three times daily, retapamulin 1% ointment twice daily,[A4] or ozenoxacin 1% cream twice daily until rash resolves are usually as effective as oral antibiotics and can reduce the likelihood of transmission of the streptococci to other individuals. Penicillin VK 500 mg four times daily for 7 days or benzathine penicillin (1.2 million units once intramuscularly) is first-line treatment for ecthyma or for impetigo present at multiple skin sites caused by streptococci. If *S. aureus* is contributing to infection, treatment should be with a penicillinase-resistant semisynthetic penicillin (e.g., dicloxacillin 500 mg orally four times daily for 7 days) or a cephalosporin (e.g., cephalexin 500 mg orally four times daily for 7 days) for methicillin-susceptible strains or doxycycline (100 mg three times daily for 7 days) or clindamycin (300 mg three times daily for 7 days) for methicillin-resistant strains. Complete recovery is the rule, but none of these treatments prevents the later development of post-streptococcal glomerulonephritis (see later).

Erysipelas

For erysipelas, treatment with oral penicillin (e.g., penicillin VK 500 mg four times daily for 10 days) or, if methicillin-sensitive *S. aureus* is of concern, oral dicloxacillin (500 mg four times daily) for a 10-day course is usually effective, and surgical debridement is not indicated. Fever, pain, and the intense redness typically diminish promptly, but the swelling may progress temporarily despite treatment. About 5 to 10 days into the illness, the involved skin typically desquamates, and healing follows.

Cellulitis

For cellulitis, oral antibiotic regimens are often as effective as intravenous regimens.[A5] Penicillin VK (500 mg orally four times daily for 10 days) is usually effective in treatment of streptococcal cellulitis. In situations in which it is difficult to differentiate between streptococcal and staphylococcal skin and soft tissue infections, a penicillinase-resistant penicillin can be used. Options include oral cephalexin (500 mg four times daily for 10 days), clindamycin (300 to 450 mg four times daily for 10 days), or trimethoprim-sulfamethoxazole (160/800 mg twice daily for 10 days),[A6] depending on the suspected pathogens, the host, and the severity of systemic toxicity. Intravenous vancomycin plus intravenous imipenem (15 to 20 mg/kg twice daily and 500 mg every 6 hours, respectively, until clinical response allows transition to oral medications) can be reserved for severe cases, when the pathogen is unclear, and when organisms such as *S. aureus* and Enterobacteriaceae are possible. In penicillin-allergic patients, a first-generation cephalosporin may be used if the hypersensitivity is non–IgE-mediated. Clindamycin, linezolid, or vancomycin may be used in patients who manifest IgE-mediated anaphylactic hypersensitivity to β-lactam antibiotics. Unless cellulitis progresses to bacteremia or to deeper soft tissue infection, most cases improve in 4 to 6 days.

Penicillin (250 mg orally twice daily) is effective for preventing recurrent cellulitis in persons who have chronic lymphedema and three or more episodes of cellulitis.

Bacteremia, Necrotizing Fasciitis, Myonecrosis, and Toxic Shock

Uncomplicated bacteremia is treated with intravenous penicillin G (4 million units every 4 hours) and intravenous clindamycin (600 to 900 mg every 8 hours). After initial stabilization with both antibiotics, the 10- to 14-day course can be completed with penicillin alone. Prognosis depends on the extent of other associated diseases such as toxic shock, deep soft tissue infection, and endocarditis.

For toxic shock syndrome, myonecrosis, and necrotizing fasciitis, management involves prompt and aggressive source control, including surgical exploration and debridement of suspected deep-seated streptococcal infections. Fluid resuscitation and early antimicrobial therapy are mandatory. Initial empirical antibiotic treatment should be broad[12] to cover for possible polymicrobial infection with (1) intravenous vancomycin plus clindamycin (15 to 20 mg/kg twice daily and 600 to 900 mg every 8 hours, respectively), (2) linezolid (600 mg twice a day),[13] or (3) tedizolid (200 mg daily),[14] *plus* either (1) piperacillin-tazobactam (3.375 g every 6 hours), (2) a carbapenem (e.g., imipenem 500 mg every 6 hours), or (3) ceftriaxone (2 g daily). Once a group A streptococcal infection is confirmed, antibiotics can be changed to treatment with both high-dose intravenous penicillin G (4 million units every 4 hours) and intravenous clindamycin (600 to 900 mg every 8 hours) for 10 to 14 days, followed by oral therapy with the total duration based on the clinical course.[15]

Even with appropriate treatment (including antibiotics, aggressive fasciotomy, and surgical debridement), mortality rates are 30 to 60% for necrotizing fasciitis and myonecrosis. In cryptic *S. pyogenes* necrotizing fasciitis or myonecrosis, the delay in diagnosis results in exceedingly high morbidity and mortality (70 to 85%).

Pneumonia

Pneumonia can be treated with amoxicillin-clavulanic acid (500-125 mg every 8 hours for 5 to 7 days). For pneumonia, mortality has generally been low with penicillin therapy and adequate drainage of empyema, but it may be higher in older patients.

Puerperal Sepsis

Treatment is intravenous penicillin G (2 million units every 4 hours). Even in the antibiotic era, the case-fatality rate is about 3.5%, in part due to delay in diagnosis.

PREVENTION

Routine secondary prophylaxis against streptococcal infection is not recommended for household contacts of index patients. Chemoprophylaxis can be considered in contacts with underlying host risk factors on a case-by-case basis. Vaccines are in development,[16] but none are currently clinically available.

POST-STREPTOCOCCAL IMMUNOLOGIC PHENOMENA

ACUTE RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Acute rheumatic fever is a result of an autoimmune response to group A streptococcal infection. Rheumatic heart disease is the long-term sequela of a single episode or repeated episodes of acute rheumatic fever (Chapter 60). The incidence of acute rheumatic fever and rheumatic heart disease is low in developed countries but continues to cause a significant burden of disease in resource-limited nations and in populations with crowded living conditions and poor access to health care. In these areas, untreated superficial *S. pyogenes* infections such as pharyngitis can lead to subsequent development of acute rheumatic fever. It is difficult to determine the incidence of acute rheumatic fever because diagnostic tools are lacking in many settings, but estimates suggest a global prevalence of about 33 million cases and about 300,000 annual deaths, with the highest rates in Oceania, South Asia, and central sub-Saharan Africa.

Acute Rheumatic Fever

EPIDEMIOLOGY

Acute rheumatic fever occurs most often in children 5 to 15 years of age.[17] Because rheumatic heart disease is often the result of recurrent infections and cumulative damage to heart valves, the peak prevalence of rheumatic heart disease is in the third and fourth decades of life. Acute rheumatic fever occurs equally in men and women, but rheumatic heart disease is more common in women.

PATHOBIOLOGY

The pathobiology of acute rheumatic fever is not entirely understood. Tissue injury is mediated through an immune mechanism that is initiated by molecular mimicry. Similarities between the infectious agent and human protein polymorphisms[18] lead to cross-activation of antibodies and T cells to human tissue. Carditis results from antibody-binding and T-cell infiltration of the heart. Transient arthritis is due to immune complexes in the joints. Chorea results from antibody binding to the basal ganglia. Skin manifestations are a result of delayed hypersensitivity reactions.

CLINICAL MANIFESTATIONS

Acute rheumatic fever develops approximately 2 weeks after the acute streptococcal pharyngitis,[19] and symptoms usually persist 2 to 4 weeks. Manifestations include fever (>90%), large-joint polyarthritis (75%), carditis (>50%), chorea (30%), subcutaneous nodules (<10%), and erythema marginatum (<10%). NSAIDs reduce arthritis pain rapidly, and the absence of symptomatic improvement with NSAIDs should prompt the clinician to think of other causes for the arthritis. The synovial fluid in acute rheumatic fever is sterile with a lymphocyte predominance. Acute rheumatic fever is typically a pancarditis that affects all parts of the heart, but the most clinically significant involvement is valvulitis of the mitral valve and, less frequently, of the aortic valve, initially with valvular regurgitation (Chapter 60). The chorea (Sydenham chorea, St. Vitus dance) of acute rheumatic fever is characterized by involuntary, nonrhythmic, and purposeless movements of the body, limbs, and face. The chorea is usually more pronounced on one side of the body. The chorea stops during sleep. Erythema marginatum is characterized by pink, nonpruritic, blanching macules or papules that spread in a serpiginous pattern on the trunk and proximal limbs. When subcutaneous nodules occur, they are usually 0.5 to 2 cm in diameter, are painless, and are seen over bony prominences or extensor tendons. Rapid sleeping pulse rate and tachycardia out of proportion to fever are occasionally observed in acute rheumatic fever.

Inflammatory markers are usually elevated, and the electrocardiogram may show a prolonged PR interval. Normochromic, normocytic anemia and leukocytosis are common.

DIAGNOSIS

There is no definitive test for acute rheumatic fever. Acute rheumatic fever is a diagnosis of exclusion, and the evaluation begins with careful assessment to exclude other causes of symptoms.

TABLE 269-3 REVISED JONES CRITERIA FOR ACUTE RHEUMATIC FEVER

A. DEFINITION	
Initial ARF	2 major or 1 major plus 2 minor criteria
Recurrent	2 major, or 1 major and 2 minor, or 3 minor
B. MAJOR CRITERIA	
LOW-RISK POPULATIONS*	**MODERATE- AND HIGH-RISK POPULATIONS**
Carditis, clinical and/or subclinical echocardiographic valvulitis	Carditis, clinical and/or subclinical echocardiographic valvulitis
Arthritis, polyarticular	Arthritis, monoarticular or polyarticular
Chorea	Chorea
Erythema marginatum	Erythema marginatum
Subcutaneous nodules	Subcutaneous nodules
C. MINOR CRITERIA	
LOW-RISK POPULATIONS	**MODERATE- AND HIGH-RISK POPULATIONS**
Polyarthralgia	Monoarthralgia
Fever ≥38.5° C	Fever ≥38.5° C
ESR ≥60 mm and/or CRP ≥3.0 mg/dL	ESR ≥30 mm and/or CRP ≥3.0 mg/dL
Prolonged PR interval (unless carditis is a major criterion)	Prolonged PR interval (unless carditis is a major criterion)

*Low-risk populations are those with an ARF incidence of <2 per 100,000 school-aged children per year or an all-age prevalence of rheumatic heart disease of ≤1 per 1000 population per year.
ARF = acute rheumatic fever; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate.
Adapted from Gewitz MH, Baltimore RS, Tani LY, et al. Revision of the Jones Criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography: a scientific statement from the American Heart Association. *Circulation*. 2015;131(20):1806-1818.

Many patients develop characteristic heart murmurs, and an echocardiogram should be considered to confirm clinical findings. Diagnosis relies on patients fulfilling a set of criteria,[20] the most commonly used of which are the Jones criteria (Table 269-3). For the purposes of the Jones criteria, low-risk populations were defined as those with an acute rheumatic fever incidence of less than 2 per 100,000 school-aged children per year or an all-age prevalence of rheumatic heart disease of 1 or less per 1000 population per year. For low-risk populations, the criteria focus on high specificity to avoid false-positive diagnosis. In populations with higher risk for acute rheumatic fever, the Jones criteria emphasize high sensitivity to reduce false-negative diagnoses.

TREATMENT AND PROGNOSIS

Persons with acute rheumatic fever should be hospitalized. Eradication of group A streptococcus from the throat and secondary prophylaxis should be accomplished with intramuscular benzathine penicillin G 1.2 million units every 4 weeks for a minimum of 10 years (and in some cases indefinitely). Other, less favorable and less effective options include oral penicillin (250 mg twice a day) or an oral macrolide (e.g., azithromycin 250 mg daily). First-line therapy for joint symptoms has traditionally been aspirin (80 to 100 mg/kg per day in divided doses to a maximum of 4 to 8 g per day), but naproxen (10 to 20 mg/kg per day divided in twice-daily doses) has been used in small studies with success. Treatment with an NSAID should continue for 1 to 2 weeks until all symptoms of acute rheumatic fever have resolved, not just the joint symptoms.

Carditis is managed by treating the associated heart failure with goal-directed therapy (e.g., diuretics, angiotensin receptor blockers; Chapter 46), fluid restriction, and bed rest. In severe cases, some experts recommend use of systemic glucocorticoids even though high-quality evidence is lacking. Valve surgery is rarely needed for acute rheumatic fever, though it can be helpful in situations of acute rupture of a valve leaflet. Rheumatic chorea usually does not require treatment and resolves within weeks to months. Despite acute treatment, about 35 to 70% of patients progress to chronic clinical rheumatic heart disease.

Rheumatic Heart Disease

Approximately 35 to 72% of patients with acute rheumatic fever develop clinical carditis, and another 18% have carditis present on echocardiogram without clinical symptoms. Some individuals with carditis have complete resolution of cardiac abnormalities, and others progress to develop rheumatic heart disease. Resolution of carditis is most likely to occur in the first year after the acute carditis.

Rheumatic heart disease, which is almost exclusively a valvular disease (Chapter 60),[21] affects the mitral valve nearly 100% of the time and the aortic valve in 20 to 30% of cases. The pulmonic valve is rarely involved, and the tricuspid valve has histologic evidence of disease in 15 to 40% of patients, but the tricuspid valve disease is not usually clinically relevant. Mitral valve regurgitation is the most common valvular pathology in rheumatic heart disease. Mitral stenosis can occur after progressive scarring of the mitral valve leaflets, and rheumatic heart disease is the most common cause of mitral stenosis worldwide. When the aortic valve is involved, regurgitation is more common than stenosis.

Most patients have classic murmurs (see Table 39-7). Echocardiography is key to diagnosis.

Patients with rheumatic heart disease should receive secondary prophylaxis,[A7] preferably as outlined previously with intramuscular benzathine penicillin G to avoid recurrent acute rheumatic fever, which can worsen rheumatic heart disease. Rheumatic heart disease is progressive, with severe valvular disease (Chapter 60) often appearing in the third or fourth decade of life. In developing countries, rheumatic heart disease remains a leading cause of bacterial endocarditis and cardiovascular morbidity and mortality. In endemic regions, echocardiographic screening can detect latent rheumatic heart disease and guide secondary prophylaxis to reduce the prevalence of progressive disease.[A8]

PEDIATRIC AUTOIMMUNE NEUROPSYCHIATRIC DISORDERS ASSOCIATED WITH STREPTOCOCCAL INFECTIONS

Group A streptococcal infections can trigger pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS), which is defined as acute onset of obsessive compulsive disorder, tics, and piano-playing choreiform movements of the fingers and toes in children after streptococcal infection.[22] Sometimes enuresis, separation anxiety, learning regression, and handwriting difficulties are also present. *S. pyogenes* infection appears to trigger development of anti-brain autoantibodies to dopamine receptors, thereby leading to neuropsychiatric symptoms in some individuals. Treatment for PANDAS includes antibiotics for primary management of infection and behavioral therapy for care of psychiatric symptoms.

POST-STREPTOCOCCAL GLOMERULONEPHRITIS

Post-streptococcal glomerulonephritis is a postinfectious, immune complex–mediated glomerulonephritis associated with prior skin or throat infection by group A streptococcus or occasionally groups C or G streptococcus (Chapter 107).[23] Post-streptococcal glomerulonephritis, like other postinfectious complications of streptococcal infection, is rare in developed countries. In developing countries, however, the annual incidence is approximately 9 cases per 100,000 population. Historically, the typical patient with post-streptococcal glomerulonephritis is a child between ages 2 and 18 years with a male-to-female ratio of 2 : 1. Immune complexes form in the glomeruli and invoke an inflammatory response, including activation of the complement system with reduction in circulating C3 levels.

The time between the initial streptococcal infection and nephritis is 7 to 10 days after throat infection and 2 to 4 weeks after skin infection. Post-streptococcal glomerulonephritis most commonly presents as nephritic syndrome with hematuria, edema, hypertension, and oliguria. Rarely, the presentation is of nephrotic syndrome or rapidly progressive crescentic glomerulonephritis. Asymptomatic disease, which is likely four to five times more common than clinically evident disease, manifests as microscopic hematuria and a fall in serum complement levels. In elderly individuals with post-streptococcal glomerulonephritis, azotemia, heart failure, and nephrotic-range proteinuria are more common than in children.

Serologic assays for antibodies to *S. pyogenes* antigens such as streptolysin O and DNase B are useful for retrospective diagnosis of antecedent *S. pyogenes* infections in cases of suspected post-streptococcal glomerulonephritis. The rise in antibodies occurs 7 to 14 days after disease onset and peaks 3 to 4 weeks after infection. The serum complement level, especially C3, is low. Renal biopsy is rarely necessary, but it should be considered when there is diagnostic doubt.

TREATMENT AND PROGNOSIS

If streptococcal infection is still present at the time of the diagnosis of post-streptococcal glomerulonephritis, benzathine penicillin G (1.2 million units intramuscularly) is indicated to treat the individual and to prevent the spread of the nephritogenic strain. Otherwise, treatment of post-streptococcal glomerulonephritis is supportive, with treatment of volume overload and hypertension with loop diuretics, salt restriction, and antihypertensive agents.

The short-term prognosis in children is excellent, and the symptoms resolve within 2 to 7 days. In adults, however, serious morbidity can occur, in part owing to preexisting cardiovascular and other diseases. Long-term development of end-stage renal disease is uncommon unless other contributors to renal disease (e.g., diabetes mellitus) are present.

STREPTOCOCCUS AGALACTIAE (GROUP B STREPTOCOCCUS)

S. agalactiae contains Lancefield group B antigen on the cell surface and is referred to as group B streptococci.

EPIDEMIOLOGY

Group B streptococci colonize the genital tract, gastrointestinal tract, and occasionally the upper respiratory tracts of normal humans. Group B streptococci cause infection in neonates, pregnant women, and nonpregnant adults, especially the elderly and patients with underlying medical disease.[24] About 9 cases of invasive group B streptococcus infection occur per 100,000 population in the United States, including neonates, children, and adults. In neonates, group B streptococci are the most common cause of pneumonia, sepsis, and meningitis in the United States and Western Europe.[25] Adults with group B streptococcus infections include postpartum women and patients who have risk factors such as diabetes, liver disease, peripheral vascular disease, or malignancy.

PATHOBIOLOGY

In the laboratory, these organisms grow as gray-white colonies that are slightly larger than for group A streptococci but cause a narrower zone of hemolysis. Definitive bacteriologic identification requires group-specific antiserum or commercial kits. The polysaccharide capsule, which is the prime virulence factor in group B streptococcus, is critical for the organism to evade phagocytosis. Defined capsular polysaccharide types of group B streptococcus are designated Ia, Ib, Ic, and II through IX. Immunity is based on the development of opsonic type-specific antibody.

CLINICAL MANIFESTATIONS

Early-onset group B streptococcus infection in children usually presents at or within 24 hours of birth but can occur anytime in the first 6 days of life. In adults, the most common clinical manifestations are soft tissue infection, osteomyelitis, and septic arthritis.[26]

TREATMENT

Intravenous penicillin G (400,000 units/kg/day in children or 4 million units every 4 hours in adults) for 10 to 14 days is the treatment of choice for group B streptococcus infections. Alternatives for penicillin-allergic patients include vancomycin (intravenously based on weight, with a goal trough of 15 to 20 μg/mL) or ceftriaxone (2 g daily for adults) for 10 to 14 days. Clindamycin (600 mg intravenously every 8 hours) can be used in penicillin-allergic adults when group B streptococcus susceptibility is known, but resistance is nearly 40% in some settings. Gentamicin (2.5 mg/kg every 8 to 24 hours based on weight and age in children or 1 mg/kg every 8 hours in adults) can be used in addition to penicillin in persons with meningitis, endocarditis, bacteremia, and severe soft tissue infections until the infection is under control.

PREVENTION

Vaccines are in development,[A9] but no licensed vaccine is available. The current approach is to provide intrapartum antimicrobial prophylaxis in women with prior delivery of an infant with invasive group B streptococcus infection, group B streptococcus bacteriuria during current pregnancy, culture evidence of vaginal or rectal group B streptococcus colonization, or unknown group B streptococcus status and either delivery before 37 weeks' gestation, duration of ruptured membranes of at least 18 hours, or intrapartum temperature of at least 100.4° F (≥38° C). All women at 35 to 37 weeks' gestation should be screened with rectal and vaginal swab for the presence of group B streptococcus unless some other indication for prophylaxis already exists. Prophylaxis begins at the onset of labor with intravenous penicillin G (5 million units loading dose, then 3 million units every 4 hours) or intravenous ampicillin (2-g loading dose, then 1 g every 4 hours) until delivery. In persons with penicillin allergy, group B streptococcus susceptibility testing for clindamycin (900 mg intravenously every 8 hours until delivery) is recommended. When susceptibility testing is not available or if the group B streptococcus is resistant to clindamycin, vancomycin (20 mg/kg intravenously every 8 hours until delivery) can be used.

STREPTOCOCCUS DYSGALACTIAE SUBSPECIES *EQUISIMILIS* (GROUP C AND GROUP G STREPTOCOCCUS)

The group C and group G streptococci that colonize the human genital tract, gastrointestinal tract, upper respiratory tract, and skin belong to a single subspecies, *S. dysgalactiae* subspecies *equisimilis*. They produce streptolysin O and a disease spectrum that resembles group A streptococci, including bacteremia, septic arthritis, skin and soft tissue infection, and pharyngitis.

TREATMENT

Treatment is with penicillin (4 million units intravenously every 4 hours) or vancomycin (15 to 20 mg/kg intravenously twice daily) for 5 to 14 days depending on the type and severity of infection. As with group A streptococcal infection, clindamycin (600 to 900 mg intravenously every 8 hours) for 10 to 14 days is used for *S. dysgalactiae* subspecies *equisimilis* infection for necrotizing fasciitis or for streptococcal toxic shock syndrome. Clindamycin should not be used initially as a single agent, however, because some *S. dysgalactiae* subspecies *equisimilis* are resistant to clindamycin. *S. dysgalactiae* subspecies *equisimilis* also may be resistant to macrolides (15 to 25% of cases) or fluoroquinolones, thereby limiting the utility of these antibiotics unless susceptibilities are known.

VIRIDANS GROUP STREPTOCOCCI (*STREPTOCOCCUS ANGINOSUS* GROUP/*STREPTOCOCCUS MILLERI* GROUP)

Viridans group streptococci include the *S. anginosus* group (also known as the *Streptococcus milleri* group). The *S. anginosus* group has three distinct species: *S. anginosus, Streptococcus constellatus,* and *S. intermedius*. Members of the *S. anginosus* group are nonmotile, facultative anaerobes that may be β-hemolytic but also may be α-hemolytic or nonhemolytic. *S. anginosus* group normally colonize the oropharynx, upper gastrointestinal tract, and appendix. Unlike *S. pyogenes* and *S. agalactiae, S. anginosus* group can cause abscess formation. Abscesses usually develop contiguous to the colonized mucosal surface as with dental or periappendiceal abscesses. Primary bacteremia, with or without endocarditis, can seed metastatic abscesses of the lung, joints, bone, and spleen. *S. intermedius* has tropism to form abscesses in the brain and liver. In patients with oral, head and neck, and abdominal infections, *S. anginosus* group may present as part of a polymicrobial infection and should be considered a true pathogen. Empyema with *S. anginosus* group is usually the result of a surgical procedure involving the respiratory or gastrointestinal tract and in most cases requires thoracotomy due to loculation of the empyema and difficulty treating with antibiotics and chest thoracostomy alone. In reviewing Gram stains of pus from such infections, these organisms characteristically show 20 to 30 gram-positive cocci within neutrophils. In the presence of bacteremia, the likelihood of bacterial endocarditis (Chapter 61) is over 30% with *S. gallolyticus, S. sanguinis*, *S. gordonii*, and *S. mutans* and about 20% with *S. mitis* or *S. oralis*.[27]

TREATMENT

Treatment of *S. anginosus* group is typically drainage of any abscess and therapy with penicillin G (4 million units intravenously every 4 hours) or another β-lactam antibiotic (e.g., cefazolin 500 to 2000 mg intravenously every 8 hours) because most isolates are susceptible to β-lactam agents. A parenteral third-generation cephalosporin (ceftriaxone 2 g intravenously twice daily) is recommended for brain abscesses and bacteremia. Vancomycin (15 to 20 mg/kg intravenously twice a day) is a reasonable alternative for penicillin-allergic patients. Resistance to fluoroquinolones, if not present initially, may develop rapidly. Many strains are developing macrolide resistance, most are resistant to aminoglycosides, and sulfonamides have no activity against *S. anginosus* group strains. *S. anginosus* is a reservoir for antimicrobial resistance genes and has been shown to transfer resistance traits to other pathogenic organisms such as *S. pyogenes* and *S. pneumoniae*.

OTHER VIRIDANS GROUP STREPTOCOCCI

More than 30 recognized species of viridans group streptococci (including *Streptococcus mitis, Streptococcus oralis, Streptococcus sanguinis, Streptococcus mutans,* and *Streptococcus gordonii*) are most commonly implicated in subacute bacterial endocarditis (Chapter 61),[28] catheter-related and neutropenia-related blood stream infections, and purulent abdominal, hepatobiliary, brain, and dental infections. Penicillin resistance in these organisms is 30 to 50% in some areas, so empirical treatment usually begins with vancomycin (15 to 20 mg/kg intravenously twice a day for 5 to 14 days, depending on severity of infection and host factors) and de-escalates to a β-lactam (e.g., penicillin G 4 million units intravenously every 4 hours) if the isolate is susceptible.

ZOONOTIC STREPTOCOCCUS

STREPTOCOCCUS SUIS

Streptococcus suis (Lancefield groups R, S, and T), which is a pathogen in pigs, can cause meningitis, sepsis, and arthritis in exposed humans. Most infections occur in individuals with extensive exposure to pigs, such as pig breeders, abattoir workers, and butchers. In this high-risk group of individuals, the annual risk for developing *S. suis* meningitis has been estimated at 1.2 to 3 cases per 100,000 population. *S. suis* is susceptible to penicillin G (4 million units intravenously every 4 hours), third-generation cephalosporins (e.g., ceftriaxone 2 g intravenously once to twice daily), and vancomycin (15 to 20 mg/kg intravenously twice a day). Duration of treatment varies from 5 to 14 days based on the severity and site of infection. In persons with meningitis due to *S. suis,* steroid treatment in addition to antimicrobials may help reduce death and disability, including hearing loss. Wearing gloves for the handling of raw pork, good hand hygiene, and thorough cooking of pork should prevent most cases of *S. suis* infection.

STREPTOCOCCUS CANIS

Streptococcus canis (Lancefield group G) is most commonly isolated from dogs, but it has been isolated also from cats, harbor porpoises, cows, mice, rats, and rabbits. Soft tissue infections and sepsis have occurred in humans, but infection is rare. Treatment is with a β-lactam antibiotic such as penicillin G (4 million units intravenously every 4 hours for 5 to 14 days based on the site and severity of infection).

STREPTOCOCCUS GALLOLYTICUS GROUP

Streptococcus gallolyticus complex bacteria are Lancefield group D nonenterococcal streptococci that colonize the intestines in 10% of healthy individuals. Subspecies include *gallolyticus, S. gallolyticus* subspecies *pasteurianus, S. gallolyticus* subspecies *macedonicus,* and *S. infantarius*. These bacteria are associated with hepatobiliary disease, meningitis, and subacute endocarditis in the setting of colorectal carcinoma. These bacteria are highly sensitive to penicillin G (4 million units intravenously every 4 hours for 5 to 14 days based on the site and severity of infection).

STREPTOCOCCUS INIAE

Streptococcus iniae is a β-hemolytic streptococcus without a Lancefield group antigen. It causes significant disease in fish, especially tilapia. Human infection results from the handling of live or killed fish. Skin and soft tissue infections are most common and often lead to bacteremia. Treatment is with a β-lactam antibiotic (e.g., penicillin G 4 million units intravenously every 4 hours for 5 to 14 days based on the site of infection).

270 ENTEROCOCCAL INFECTIONS

PATRICE SAVARD AND TRISH M. PERL

DEFINITION

Enterococci are endogenous human gut flora that are increasingly important health care–associated pathogens. Enterococci cause urinary tract infections, bacteremia, intra-abdominal infections, and, rarely, endocarditis and meningitis. Their emergence as major pathogens results from their inherent resistance to commonly used antimicrobial agents, persistence in the environment, association with indwelling devices, and transmission from patient to patient, mostly by way of the contaminated hands of health care personnel.

The Pathogen

Enterococci are catalase-negative gram-positive cocci that can appear singly, in pairs, or in short chains. They are facultative anaerobes that grow optimally at 35° to 37° C on sheep blood agar as α-hemolytic or nonhemolytic organisms. Unlike most streptococci, enterococci can grow in broth containing 6.5% NaCl and hydrolyze esculin in the presence of 40% bile salts (bile-esculin medium). *Enterococcus faecalis* is the causative agent for 80 to 90% of human enterococcal infections, followed by *Enterococcus faecium* (5 to 10% of the infections). *Enterococcus casseliflavus, Enterococcus gallinarum*, and *Enterococcus raffinosus* are less frequently associated with infections, but clusters have been reported. Other species isolated from humans include *Enterococcus avium, Enterococcus caccae, Enterococcus cecorum, Enterococcus dispar, Enterococcus durans, Enterococcus gilvus, Enterococcus hawaiiensis, Enterococcus hirae, Enterococcus italicus, Enterococcus malodoratus, Enterococcus massiliensis, Enterococcus mediterraneensis, Enterococcus mundtii, Enterococcus pallens, Enterococcus pseudoavium, Enterococcus thailandicus,* and *Enterococcus timonensis*.

EPIDEMIOLOGY

Enterococci are part of the normal human gut flora, and infections in both hospitalized and non-hospitalized patients can arise from either an endogenous or exogenous source. The proportion of infections caused by enterococci in hospitalized patients has increased over the past several decades. Overall, urinary tract infections (Chapter 263) are the most common clinical condition caused by enterococci. Enterococcal species also are the second most common isolates for any health care–associated infection (Chapter 261) and the single most common cause of central line–associated blood stream infections in patients who are hospitalized on regular hospital floors, intensive care units (ICUs), and inpatient oncology units.[1] Enterococci also cause about 15% of both catheter-associated urinary tract infections and surgical site infections in North America. In community settings, enterococci cause both complicated and uncomplicated urinary tract infections and are involved in approximately 5 to 15% of all cases of infective endocarditis (Chapter 61). Outside of the United States, these organisms are less common but increasingly important causes of infections.

Enterococcus species, especially *E. faecium,* in hospitalized patients increasingly may be resistant to vancomycin, ampicillin, or gentamicin. By 2017, 82% of *E. faecium* isolates and 7% of *E. faecalis* isolates from health care–associated infections were resistant to vancomycin. Vancomycin-resistant enterococci are associated with about 55,000 infections in hospitalized patients and 5400 deaths in the United States, each year. Although the proportion of vancomycin resistance among enterococcal clinical isolates in hospitalized patients has been historically lower in Europe than in the United States, about 18% of all European *E. faecium* isolates were resistant to vancomycin in 2019, with the prevalence varying from 0 to 50% in individual countries.

Most vancomycin-resistant enterococcus infections are associated with health care (Chapter 261), especially hospitalization in the prior year, and result from either an exogenous source (i.e., transmission from the environment, another patient, or the hands of health care personnel) or antimicrobial exposure.[2] Nearly all infections are preceded by a period of colonization, primarily in the gastrointestinal tract, where patients may harbor the strain for years after colonization. Although many colonized patients do not develop infections, they are still able to contaminate the environment, shed and transmit bacteria to other hospitalized patients, and precipitate an outbreak.

Apart from preexisting gastrointestinal colonization, risk factors for enterococcal infections, particularly vancomycin-resistant infections, include severe underlying conditions such as renal failure (Chapter 116), previous solid organ (especially liver; Chapter 140) or hematopoietic stem cell transplantation (Chapter 163), solid tumor and hematologic malignancies, diabetes mellitus (Chapter 210), and neutropenia (Chapter 153). Other factors associated with infection include prior surgical or gastrointestinal procedures, presence of a vascular or urinary indwelling catheter, hospital factors such as location in an ICU or an inpatient oncology service, proximity to colonized patients, prolonged length of hospitalization, and recent exposure to antimicrobial agents.[3]

Most classes of antimicrobials increase the risk of colonization with vancomycin-resistant enterococcus and subsequent clinical infections, but vancomycin, cephalosporins, and drugs that cure anaerobic organisms are especially implicated. Colonization with vancomycin-resistant enterococcus may coexist with *Clostridioides difficile* (Chapter 271) infection in high-risk patients, such as inpatients with hematologic malignancies.

PATHOBIOLOGY

Enterococci are commensal organisms that colonize the human gastrointestinal tract and female genital tract. They contaminate and also can be recovered from the environment. Although they are not as intrinsically virulent as other gram-positive pathogens, under certain conditions the commensal relationship is disrupted and serious infections occur. Several adhesion factors have been identified, including aggregation substance, which allow binding to epithelial surfaces and enhance the ability for colonization. The ability to adhere to heart valves and urinary tract epithelium enables enterococci to cause endocarditis and urinary tract infections. Enterococci are also known to secrete potential virulence factors, including cytolysin-hemolysin, which is a bacterial toxin that is produced in a higher proportion of infecting strains compared with stool-colonizing strains. Infecting strains also possess the ability to translocate across the intestinal epithelium, although the exact mechanisms of this process have yet to be determined. In addition, some encoded cell surface determinants may mediate adherence to host tissues that may be important in this organism's role in endocarditis. The exact role of capsular polysaccharides in colonization or infection is unknown. Strains have been shown to survive within phagocytic cells, yet it is unclear whether this represents successful host defense or evasion by the enterococci.

The intrinsic resistance to multiple antimicrobials (including cephalosporins, clindamycin, trimethoprim-sulfamethoxazole, and low-level aminoglycosides) that enterococci possess, along with their ability to acquire resistance to a wide range of antibiotics (including high concentrations of penicillins, fluoroquinolones, tetracycline, nitrofurantoin, and glycopeptides) through mutation or acquisition of new genes, enhances their ability to survive and multiply in the many hospitalized patients treated with broad-spectrum antimicrobials.

In the 21st century, additional antimicrobial resistance has emerged primarily in *E. faecium*. Two major genotypes, VanA and VanB, are responsible for acquired vancomycin resistance. The genes encoding the VanA phenotype, which also result in high-level resistance to teicoplanin, are carried on a plasmid or a conjugative transposon that is transferable. VanA is mostly found in *E. faecium* and, less frequently, in *E. faecalis*. VanB is associated with variable resistance to vancomycin, but isolates are usually susceptible to teicoplanin.

VanA and VanB are rarely found in other enterococci, but VanC is intrinsically recovered from *E. casseliflavus* and *E. gallinarum*. Importantly, these genetic elements have been integrated into the genome of *S. aureus* (Chapter 267) that is resistant to vancomycin. Resistance to ampicillin and high-level resistance to gentamicin have also been reported (Chapter 258).

CLINICAL MANIFESTATIONS

Enterococci cause urinary tract infections, intra-abdominal abscesses, wound infection, bacteremia (including central line–associated blood stream infections), endocarditis, and meningitis, but no specific clinical manifestations can help distinguish enterococcal infections from infections caused by other bacteria. Enterococci are not thought to cause lower respiratory tract infections and, if found in this setting, likely represent colonization and not infection. Enterococci act as opportunistic pathogens in severely ill and compromised patients, and fecal proliferation of enterococci has been implicated in graft-versus-host disease after hematopoietic stem cell transplantation (Chapter 163).[4]

Urinary Tract Infections

Urinary tract infections (Chapter 263) are the most frequent type of infection caused by enterococci. Most infections are nosocomial in origin (Chapter 261), and include uncomplicated cystitis, pyelonephritis, prostatitis (Chapter 114), and perinephric abscess. These infections are typically secondary to urinary catheterization or instrumentation.[5] In contrast to health care–associated

ABSTRACT

Enterococci, which colonize the gastrointestinal and urinary tracts, are inherently resistant to many classes of antimicrobials. They commonly cause urinary tract infections primarily after instrumentation, bloodstream infections associated with or without catheters, and intra-abdominal and postsurgical infections. They can cause endocarditis, which requires careful antimicrobial therapy. The most common species include *Enterococcus faecalis* and *E. faecium. E. faecium,* which is primarily a pathogen in immunocompromised hosts, is often resistant to vancomycin and other glycopeptides. Therapy with penicillin-based agents with or without aminoglycosides are associated with the best outcomes. For vancomycin-resistant organisms, however, antimicrobials such as linezolid and daptomycin play an important role. New combination therapies, including cephalosporins (ceftriaxone or ceftaroline or cefepime), are under study for endocarditis. As with many organisms, drainage of the source and removal of any indwelling catheters are key to improved outcomes.

KEYWORDS

Enterococcus faecalis
Enterococcus faecium
vancomycin-resistant *Enterococcus* (VRE)
urinary tract infection
bacteremia
endocarditis

urinary tract infections, enterococci cause fewer than 5% of uncomplicated cystitis or pyelonephritis cases in otherwise healthy non-hospitalized women. Patients with diabetes mellitus appear to be at increased risk for enterococcal urinary tract infections, but enterococcal bacteremia is infrequently associated with urinary tract infections.

Bacteremia

Enterococci can cause infection or contaminate cultured blood via contaminated catheter hubs and contaminated skin. Determining a true bacteremia versus a blood culture that is not clinically significant can be a challenge (Chapter 256). Specific risk factors include prolonged hospitalization, preexisting urethral catheters or intravascular lines, recent surgery, malignancy, neutropenia, and biliary tract disease.[6] Secondary bacteremia without endocarditis usually arises from the urinary tract, hepatobiliary tract, or soft tissue infection. Risk factors for bacteremia with vancomycin-resistant enterococci are similar but additionally include severe preexisting comorbid conditions, including hematologic malignancy, human immunodeficiency virus (HIV) infection, chronic renal insufficiency, and liver transplantation. Prior exposure (and especially prolonged exposure) to broad-spectrum antimicrobial drugs, particularly multiple drugs with antianaerobic activity (e.g., clindamycin, metronidazole, and piperacillin/tazobactam), is a consistent risk factor.

When enterococci are isolated alone, the course is typically indolent, and fever frequently is the only sign. Enterococcal bacteremia is frequently polymicrobial and more severe, often presenting with shock (Chapter 94) or disseminated intravascular coagulation (Chapter 161).

Endocarditis

Enterococci, particularly *E. faecalis,* are an important cause of endocarditis[7] (Chapter 61) and represent at least 10% of cases in non–intravenous drug users. About 25% of patients with *E. faecalis* bacteremia have definitive bacterial endocarditis,[8] and about 50% of patients with *E. faecalis* endocarditis have a colorectal neoplasm discovered.[9] The disease occurs most frequently in older patients, with a male predominance. Most cases appear to arise in the community. Patients with preexisting valvular heart disease (Chapter 60), including prosthetic valves, are at highest risk, but many patients do not have underlying heart disease. Enterococci more commonly cause left-sided endocarditis, primarily affecting the mitral valve. Patients typically present with subacute bacterial endocarditis symptoms for weeks or months, similar to the clinical presentation of streptococcal viridans endocarditis, before seeking medical care.

Intra-abdominal Infections

In intra-abdominal infections, enterococci are often detected as part of a polymicrobial process. These infections typically arise from a hepatobiliary source (Chapter 141), including complicated biliary stone disease and postoperative infection after liver transplantation (Chapter 140), and are complicated by hepatic abscess formation[10] and secondary bacteremia.

Skin and Soft Tissue Infections

Enterococci rarely cause cellulitis or other skin and soft tissue infections alone but are often found in mixed surgical site infections, diabetic foot infections, and decubitus ulcers along with other gram-negative bacilli, gram-positive cocci, and anaerobic bacteria. Their clinical significance in these situations is not clear. Enterococci are not thought to be primary pathogens in chronic osteomyelitis. When identified, they likely represent superinfection, so antimicrobial therapy may not require antibiotics directed at enterococcal eradication.

DIAGNOSIS

The tentative diagnosis of an *Enterococcus* infection can be made rapidly by nucleic acid testing and confirmed by isolating the organism by culture of a sterile site, such as blood or urine.

TREATMENT

Because of the complexity of enterococcal infections, an infectious diseases consultation should be considered for therapeutic guidance. For any severe enterococcal infection, empirical therapy should generally be based on the site of infection, the patient population, and local epidemiology (Table 270-1). Once susceptibility testing by an experienced microbiology laboratory is available, the results can guide effective directed therapy.

Optimal therapy for most infections includes intravenous ampicillin, penicillin, or vancomycin. Except for urinary tract infections or skin and soft tissue infections, standard therapy with penicillins and vancomycin should also include the addition of a synergistic aminoglycoside (i.e., gentamicin or streptomycin), especially for suspected endocarditis, provided that high-level resistance is not detected. Neither tobramycin nor kanamycin has synergistic activity against enterococci. Oritavancin and dalbavancin are active against vancomycin-susceptible enterococci and can be considered in skin and soft tissue infections (see Table 270-1).

E. faecium strains increasingly are resistant to penicillins, but most *E. faecalis* strains remain susceptible to ampicillin and the related piperacillin. Even when enterococcus appears susceptible to trimethoprim-sulfamethoxazole in vitro, it should not be used because clinical failures have been reported secondary to the ability of enterococci to use exogenous folate. *E. faecalis* is intrinsically resistant to quinupristin-dalfopristin, which therefore should not be used in therapy for infections caused by this species, as opposed to *E. faecium,* which remains susceptible to that drug.

For vancomycin-resistant enterococcal strains, potential agents include linezolid, tigecycline, daptomycin, and tedizolid. Linezolid, which is bacteriostatic against enterococci, is commonly the drug of choice for infections other than bacteremia,[A1] although it is associated with bone marrow suppression, including thrombocytopenia, and can cause the serotonin syndrome when used in combination with selective serotonin re-uptake inhibitors (Chapter 400). Although daptomycin is not approved by the U.S. Food and Drug Administration (FDA) to treat vancomycin-resistant enterococcus, it has been associated with good outcomes in skin and soft tissue infections and bacteremia. Tigecycline is FDA-approved to treat complicated skin and soft tissue infections and complicated intra-abdominal infections caused by vancomycin-susceptible isolates of *E. faecalis*, but an FDA-required black box warning about potentially worsened overall outcome limits its use.

Urinary Tract Infections

Single-agent therapy is usually adequate to treat enterococcal urinary tract infections. Options include ampicillin, amoxicillin, penicillin, quinolones, fosfomycin, or vancomycin (see Table 270-1). Based on pharmacodynamic data, aminopenicillins may be useful even when isolates are resistant because of their high urinary concentrations, but clinical data are very limited.[11] Vancomycin is typically reserved for penicillin-allergic patients or if the strain has high-level penicillin/ampicillin resistance. β-Lactam–β-lactamase inhibitor combinations are usually reserved for polymicrobial infections. Nitrofurantoin is also occasionally used because most strains, even if vancomycin-resistant, remain susceptible. Fosfomycin is also effective for urinary tract infections caused by susceptible *E. faecalis*.

Bacteremia without Endocarditis

Many cases of enterococcal bacteremia are transient or self-limited, but antibiotic therapy with penicillin or ampicillin (see Table 270-1) improves outcomes, especially when instituted within 48 hours.[12] Daptomycin treatment of daptomycin-susceptible, vancomycin-resistant enterococcal blood stream infections is more effective with higher daptomycin doses (≥9 mg/kg). Unlike in endocarditis, it is not known whether patients benefit from combination therapy (penicillin or ampicillin or vancomycin plus an aminoglycoside), except perhaps when an intravascular catheter is present. In the setting of an intravascular catheter, especially for VRE, removal of the catheter is indicated. If the bacteremia is secondary to another site such as an intra-abdominal abscess, drainage of the source is critical to cure.

Endocarditis

Combination therapy (intravenous penicillin, ampicillin, or vancomycin plus an aminoglycoside) with bactericidal activity to sterilize vegetations is the standard therapy for enterococcal endocarditis (Chapter 61). Another synergistic combination for patients who cannot tolerate aminoglycosides includes ampicillin plus ceftriaxone or cefotaxime to treat *E. faecalis* endocarditis but not *E. faecium*.[13,14] Adding ampicillin and ceftaroline to daptomycin may be better than daptomycin monotherapy.

If the causative enterococcal strain is highly resistant to both gentamicin and streptomycin, then alternative agents and durations must be explored, and surgery to excise infected valves should be considered. Optimal therapy of vancomycin-resistant enterococcus strains that are resistant to ampicillin is not known; options include linezolid (not FDA-approved for endocarditis treatment) and daptomycin (not FDA-approved for enterococcal infections) if the strain is found to be susceptible. However, linezolid resistance is increasingly reported even in patients without previous exposure to the antibiotic, and daptomycin resistance is also reported in both *E. faecalis* and *E. faecium* after prolonged courses of therapy.

Vancomycin-resistant enterococcal endocarditis (Chapter 61) may require early surgery because outcomes with antibiotic therapy alone can be poor. If repeated blood cultures grow for more than 7 days after the initiation of medical therapy or other signs of uncontrolled infection (persistent fever or leukocytosis) are present, valve replacement should be considered early in the treatment course if there are no absolute contraindications for surgery.

Switching from intravenous to oral medications after 10 days of therapy may be safe[A2] for *E. faecalis* endocarditis but should be carefully evaluated in consultation with an infectious diseases specialist. The overall duration of therapy is typically 4 to 6 weeks, with longer therapy in patients who had prolonged symptoms before seeking therapy, have prosthetic valve infection, or relapse after initial treatment.

TABLE 270-1 TREATMENT OPTIONS FOR DIFFERENT ENTEROCOCCAL SPP FOR VARIOUS INFECTION SITES[‖]

	ENTEROCOCCUS FAECALIS	*ENTEROCOCCUS FAECIUM*	VANCOMYCIN-RESISTANT ENTEROCOCCUS (VRE)
Urinary Tract Infection			
PCN/ampicillin susceptible*	Ampicillin (1 g IV q6h) or amoxicillin (500 mg PO TID)	Ampicillin (1 g IV q6h) or amoxicillin (500 mg PO TID)	Ampicillin (1 g IV q6h) or amoxicillin (500 mg PO TID) Fosfomycin if susceptible (3 g PO once if catheter removed)
PCN/ampicillin resistance*	If susceptible: nitrofurantoin (100 mg PO q12h†) or fosfomycin (3 g PO once if catheter removed) if uncomplicated§ Vancomycin if resistant to other agents	If susceptible: nitrofurantoin (100 mg PO q12h†) Vancomycin if resistant to other agents	If susceptible: nitrofurantoin (100 mg PO q12h†) Linezolid (600 mg PO/IV q12h) or Daptomycin (8-12 mg/kg IV q24h) or Fosfomycin if susceptible (3 g PO once if catheter removed) if uncomplicated§
Bacteremia*			
PCN/ampicillin susceptible*	PCN (4 million IV q4h) or ampicillin (2 g IV q4-6h) for 7-14 days	PCN (4 million IV q4h) or ampicillin (2 g IV q4-6h) for 7-14 days	Consider consultation with an infectious diseases specialist PCN (4 million IV q4h) or ampicillin (2 g IV q4-6h) if susceptible
With PCN allergy or PCN/ampicillin resistance	Vancomycin load with 20-25 mg/kg followed by 15-20 mg/kg q8-12h based on PK/PD dosing using actual body weight to achieve a serum level of 15-20 µg/mL (trough) Consider adding gentamicin if prolonged bacteremia and laboratory reports synergy with cell wall–active agent	Vancomycin load with 20-25 mg/kg followed by 15-20 mg/kg q8-12h based on PK/PD dosing using actual body weight to achieve a serum level of 15-20 µg/mL (trough) Consider adding gentamicin if prolonged bacteremia and laboratory reports synergy with cell wall–active agent	Linezolid (600 mg PO/IV q12h) or Daptomycin (8-12 mg/kg IV q24h) for 14 days
Endocarditis††			
PCN/ampicillin and aminoglycoside susceptible*	Consider consultation with an infectious diseases specialist Combination therapy indicated PCN (4 million IV q4h) or ampicillin (2 g IV q4h) PLUS gentamicin (3 mg/kg IV q24h) both for 4‡-6 wk Ampicillin (2 g IV q4h) PLUS ceftriaxone (2 g IV q12h) or cefotaxime (2 g IV q8h) for 6 wk	Consult an infectious diseases specialist Combination therapy indicated PCN (4 million IV q4h) or ampicillin (2 g IV q4h) PLUS gentamicin (3 mg/kg IV q24h) both for 4‡-6 wk	Consult an infectious diseases specialist Combination therapy indicated PCN (4 million IV q4h) or ampicillin (2 g IV q4h) PLUS gentamicin (3 mg/kg IV q24h) both for 6 wk
PCN/ampicillin susceptible and gentamicin resistant* or gentamicin intolerant	Consult an infectious diseases specialist Combination therapy indicated: (1) ampicillin (2 g IV q4h) PLUS ceftriaxone (2 g IV q12h) or cefotaxime (2 g IV q8h) either for 6 wk or (2) PCN (4 million IV q4h) or ampicillin (2 g IV q4h) PLUS streptomycin† (7.5 mg/kg IV or IM q12h) for 4‡-6 wk	Consult an infectious diseases specialist Combination therapy indicated PCN (4 million IV q4h) or ampicillin (2 g IV q4h) PLUS streptomycin† (7.5 mg/kg IV or IM q12h) both for 4‡-6 wk	Consult an infectious diseases specialist Combination therapy indicated PCN (4 million IV q4h) or ampicillin (2 g IV q4h) PLUS streptomycin† (7.5 mg/kg IV or IM q12h) both for 6 wk

PCN/ampicillin resistant and gentamicin susceptible*	Consult an infectious diseases specialist Vancomycin load with 20-25 mg/kg followed by 15-20 mg/kg q8-12h based on PK/PD dosing using actual body weight to achieve a serum level of 15-20 µg/mL (trough) PLUS gentamicin (1 mg/kg IV q8h) both for 6 wk	Consult an infectious diseases specialist Vancomycin load with 20-25 mg/kg followed by 15-20 mg/kg q8-12h based on PK/PD dosing using actual body weight to achieve a serum level of 15-20 µg/mL (trough) PLUS gentamicin (1 mg/kg IV q8h) both for 6 wk	Consult an infectious diseases specialist Linezolid (600 mg PO/IV q12h) PLUS another active agent or Daptomycin 8-12 mg/kg IV q24h PLUS gentamicin (1 mg/kg IV q8h) both for 6 wk Consider other combinations including daptomycin + ampicillin or ceftaroline**
PCN/ampicillin resistant and gentamicin resistant*	Consult an infectious diseases specialist Linezolid (600 mg PO/IV q12h) or Daptomycin (8-12 mg/kg IV q24h) for a minimum of 6 wk Consider combination of daptomycin with either ampicillin or ceftaroline** 600 mg IV q 8–12 h Failures reported; consider surgery	Consult an infectious diseases specialist Linezolid (600 mg PO/IV q12h) or Daptomycin (8-12 mg/kg IV q24h) for a minimum of 6 wk Consider combination of daptomycin with either ampicillin or ceftaroline** 600 mg IV q 8–12 h Failures reported; consider surgery	Consult an infectious diseases specialist Linezolid (600 mg PO/IV q12h) PLUS another active agent or Daptomycin (8-12 mg/kg IV q24h) for 6 wk Consider combination with either ampicillin or ceftaroline** 600 mg IV q 8–12 h Failures reported; consider surgery
Intra-abdominal/Skin and Soft Tissue Polymicrobial Infections			
PCN/ampicillin susceptible*	Ampicillin-sulbactam 1.5-3 g IV q 6 h OR Piperacillin-tazobactam 3.375 g IV q6h Other combinations can be used based on a consultation with infectious diseases specialist	Ampicillin-sulbactam 1.5-3 g IV q 6 h OR Piperacillin-tazobactam 3.375 g IV q 6 h Other combinations can be used based on a consultation with infectious diseases specialist	Ampicillin-sulbactam 1.5-3 g IV q 6 h OR Piperacillin-tazobactam 3.375 g IV q 6 h Other combinations can be used based on a consultation with infectious diseases specialist
PCN/ampicillin resistance*	Combine vancomycin PLUS other antimicrobials covering the primary pathogens	Combine vancomycin PLUS other antimicrobials covering the primary pathogens	Consult an infectious diseases specialist Linezolid (600 mg PO/IV q12h) PLUS another active agent or Daptomycin (8-12 mg/kg IV q24h) PLUS other antimicrobials covering the primary pathogens

IM = intramuscular; IV = intravenous; PCN = penicillin; PO = oral; q = every; TID = three times a day; UTI = urinary tract infection. Dose adjustment of most antibiotics is required in case of renal dysfunction. PK/PD = pharmacokinetic and pharmacodynamic dosing.

*Refer to the most recent guidelines for susceptibility cutoff values.

†Do not use with creatinine clearance less than 50 mL/min.

‡Treat for 4 weeks only when symptoms have been present for less than 3 months and there is a prompt response to therapy.

§For complicated UTI use 3 g (1 sachet) PO every 2-3 days (up to 21 days).

‖Doses are for normal renal function.

**Not FDA-approved for enterococcal infections.

††For prosthetic valve endocarditis, consult infectious diseases specialist.

Intra-abdominal and Skin and Soft Tissue Infections
Because intra-abdominal and skin and soft tissue infections involving *Enterococcus* spp are commonly polymicrobial, specific anti-enterococcal therapy is usually not required.[15] If enterococci are thought to be a significant pathogen, a broad-spectrum β-lactam antibiotic (if susceptible) is preferred to cover a polymicrobial infection.

PRIMARY PREVENTION

Optimal infection prevention for vancomycin-resistant enterococcus, similar to many multidrug-resistant bacteria, includes proper use and compliance with hand hygiene, use of contact precautions, cohorting of colonized patients, proper management and timely removal of urinary and vascular catheters, reduction of antibiotic selective pressure through antimicrobial stewardship, and environmental cleaning of equipment and patient rooms (Chapter 261). Because vancomycin-resistant enterococci contaminate and persist in the environment for long periods of time, environmental cleaning is particularly important for preventing infections.

Since the number of patients already colonized with vancomycin-resistant enterococci in a defined geographic area ("colonization pressure") may be the most significant predictor of new acquisition of vancomycin-resistant enterococci, decontamination of patients' skin, called source control, may broadly control transmission of resistant pathogens and reduce device-related infections. Source control using daily bathing of ICU patients with chlorhexidine gluconate–saturated cloths has shown benefit in most studies, and sustained and appropriate application of chlorhexidine may also be beneficial in non–critical care inpatients in settings with high rates of vancomycin-resistant enterococcus or methicillin-resistant *Staphylococcus aureus*.[A3]

Because nearly all enterococcal infections are preceded by gastrointestinal colonization, because only 1 in 10 colonized patients is symptomatic, and because colonized patients can shed and transmit bacteria to other hospitalized patients, unrecognized colonized patients represent the target population for infection prevention and control. Active surveillance programs use rectal surveillance swabs to detect previously unrecognized colonized patients and isolate them to prevent further transmission. Surveillance cultures or PCR may be recommended at the time of hospital admission for patients at high risk for carriage of vancomycin-resistant enterococcus, and colonized patients or infected patients should be placed in isolation using contact precautions. Contact precautions typically entail private rooms and dedicated equipment such as stethoscopes. By comparison, the use of gloves and gowns does not appear to reduce the acquisition of vancomycin-resistant enterococcus (or methicillin-resistant *S. aureus*)[A4] compared with standard precautions, which include cleaning and disinfection of equipment that is used in patient rooms.

PROGNOSIS

Focal enterococcal infections other than intra-abdominal infections are curable with antibiotics. Enterococcal bacteremia, however, is associated with prolonged hospitalization and added costs compared with similar patients without enterococcal bacteremia. Bacteremia secondary to an intra-abdominal source carries an especially high mortality rate. Vancomycin-resistant enterococcal bacteremia has about a 20%[16] or higher in-hospital mortality rate, which is about twice the mortality rate of bacteremia caused by susceptible organisms. Appropriate antibiotic treatment of bacteremia within 48 hours is associated with better outcomes, and the higher mortality may be related to a delay in the administration of adequate empirical antibiotic therapy.

271 CLOSTRIDIAL AND *CLOSTRIDIOIDES* INFECTIONS

MARK H. WILCOX AND ERIK R. DUBBERKE

DIARRHEAL SYNDROMES
CLOSTRIDIOIDES DIFFICILE INFECTION

DEFINITION

The hallmark of *C. difficile* infection is diarrhea, most commonly during or after (up to 3 months) a course of antibiotics. Most cases are defined by the presence of clinically significant diarrhea (three or more loose or unformed bowel movements per day) plus evidence of toxigenic *C. difficile* or its toxins A and/or B in stool. *C. difficile* infection can also be diagnosed by direct visualization of colonic pseudomembranes on endoscopy.

The Pathogen

C. difficile is a spore-forming, anaerobic, gram-positive bacilli that is ubiquitous in nature around the world. Production of toxin B is required for *C. difficile* to cause *C. difficile* infection (toxigenic strains), but not all strains of *C. difficile* have the gene for toxin B (nontoxigenic strains).

EPIDEMIOLOGY

C. difficile has a worldwide distribution. It has been isolated from soil, water, homes of otherwise healthy people, retail establishments, meat and vegetables purchased at grocery stores, and the feces of pets, livestock, and wild animals. Upwards of 50% of asymptomatic infants are colonized with *C. difficile* at any one point in time, as are 10 to 25% of toddlers. Approximately 3% of healthy, asymptomatic adults are colonized with *C. difficile*, but the colonization prevalence of toxigenic *C. difficile* in hospitalized adults can be as high as 20%.[1] Although ambulatory adults are less likely than children to be colonized with *C. difficile*, clinical *C. difficile* infection is very uncommon in children, but the incidence increases with age, especially among people over age 60 years. For community-associated cases, new infections are mostly a result of the new acquisition of the organism followed by intestinal colonization. Most cases of health care–onset *C. difficile* infection are a result of a new acquisition of *C. difficile* after an antibiotic exposure, with a median of 3 to 7 days from the acquisition of *C. difficile* to the onset of infection.

The incidence and severity of *C. difficile* infection increased dramatically in the first decade of the 21st century, associated with a new predominant ribotype 027 strain, which was associated with dramatic outbreaks in North America and Europe. This strain, which is highly fluoroquinolone-resistant, produces a third toxin (binary toxin) and is readily transmissible in the health care setting. From 2011 to 2017, a 36% decline in the number of cases of health care–associated *C. difficile* infection (Chapter 261; from about 305,000 to about 195,000) have been associated with declines in the proportion of cases due to the 027 strain, from nearly 35% in 2011 to only 15% by 2017. This decline was likely due to improved antimicrobial stewardship and a focus on preventing *C. difficile* transmission in hospitals.[2,3] Similar declines have been noted in community-associated *C. difficile* infection cases due to the 027 strain over the same time period, but cases of community-associated *C. difficile* infection have remained constant at about 170,000 per year, apparently because of the ubiquity of *C. difficile* in the community and the stable or even increased prescribing of outpatient antibiotics.[4]

PATHOBIOLOGY

As a strict anaerobe, vegetative *C. difficile* cells die after exposure to oxygen. Its spores, however, can survive for months in the external environment and lead to colonization. The normal adult gut microbiota provides the first line of defense against *C. difficile* colonization and infection, and the decline in colonization from infancy to adolescence mirrors the maturation of the gut microbiome.[5] The metabolic activity of the healthy microbiome and competition for nutrients and binding sites determine whether *C. difficile* will colonize after an exposure and whether colonization will progress to clinical infection. For example, the microbiome converts primary bile salts, which are excreted into the bowel from the liver, into secondary bile salts that prevent *C. difficile*

Intra-abdominal and Skin and Soft Tissue Infections
Because intra-abdominal and skin and soft tissue infections involving *Enterococcus* spp are commonly polymicrobial, specific anti-enterococcal therapy is usually not required.[15] If enterococci are thought to be a significant pathogen, a broad-spectrum β-lactam antibiotic (if susceptible) is preferred to cover a polymicrobial infection.

PRIMARY PREVENTION

Optimal infection prevention for vancomycin-resistant enterococcus, similar to many multidrug-resistant bacteria, includes proper use and compliance with hand hygiene, use of contact precautions, cohorting of colonized patients, proper management and timely removal of urinary and vascular catheters, reduction of antibiotic selective pressure through antimicrobial stewardship, and environmental cleaning of equipment and patient rooms (Chapter 261). Because vancomycin-resistant enterococci contaminate and persist in the environment for long periods of time, environmental cleaning is particularly important for preventing infections.

Since the number of patients already colonized with vancomycin-resistant enterococci in a defined geographic area ("colonization pressure") may be the most significant predictor of new acquisition of vancomycin-resistant enterococci, decontamination of patients' skin, called source control, may broadly control transmission of resistant pathogens and reduce device-related infections. Source control using daily bathing of ICU patients with chlorhexidine gluconate–saturated cloths has shown benefit in most studies, and sustained and appropriate application of chlorhexidine may also be beneficial in non–critical care inpatients in settings with high rates of vancomycin-resistant enterococcus or methicillin-resistant *Staphylococcus aureus*.[A3]

Because nearly all enterococcal infections are preceded by gastrointestinal colonization, because only 1 in 10 colonized patients is symptomatic, and because colonized patients can shed and transmit bacteria to other hospitalized patients, unrecognized colonized patients represent the target population for infection prevention and control. Active surveillance programs use rectal surveillance swabs to detect previously unrecognized colonized patients and isolate them to prevent further transmission. Surveillance cultures or PCR may be recommended at the time of hospital admission for patients at high risk for carriage of vancomycin-resistant enterococcus, and colonized patients or infected patients should be placed in isolation using contact precautions. Contact precautions typically entail private rooms and dedicated equipment such as stethoscopes. By comparison, the use of gloves and gowns does not appear to reduce the acquisition of vancomycin-resistant enterococcus (or methicillin-resistant *S. aureus*)[A4] compared with standard precautions, which include cleaning and disinfection of equipment that is used in patient rooms.

PROGNOSIS

Focal enterococcal infections other than intra-abdominal infections are curable with antibiotics. Enterococcal bacteremia, however, is associated with prolonged hospitalization and added costs compared with similar patients without enterococcal bacteremia. Bacteremia secondary to an intra-abdominal source carries an especially high mortality rate. Vancomycin-resistant enterococcal bacteremia has about a 20%[16] or higher in-hospital mortality rate, which is about twice the mortality rate of bacteremia caused by susceptible organisms. Appropriate antibiotic treatment of bacteremia within 48 hours is associated with better outcomes, and the higher mortality may be related to a delay in the administration of adequate empirical antibiotic therapy.

271 CLOSTRIDIAL AND *CLOSTRIDIOIDES* INFECTIONS

MARK H. WILCOX AND ERIK R. DUBBERKE

DIARRHEAL SYNDROMES
CLOSTRIDIOIDES DIFFICILE INFECTION

DEFINITION

The hallmark of *C. difficile* infection is diarrhea, most commonly during or after (up to 3 months) a course of antibiotics. Most cases are defined by the presence of clinically significant diarrhea (three or more loose or unformed bowel movements per day) plus evidence of toxigenic *C. difficile* or its toxins A and/or B in stool. *C. difficile* infection can also be diagnosed by direct visualization of colonic pseudomembranes on endoscopy.

The Pathogen

C. difficile is a spore-forming, anaerobic, gram-positive bacilli that is ubiquitous in nature around the world. Production of toxin B is required for *C. difficile* to cause *C. difficile* infection (toxigenic strains), but not all strains of *C. difficile* have the gene for toxin B (nontoxigenic strains).

EPIDEMIOLOGY

C. difficile has a worldwide distribution. It has been isolated from soil, water, homes of otherwise healthy people, retail establishments, meat and vegetables purchased at grocery stores, and the feces of pets, livestock, and wild animals. Upwards of 50% of asymptomatic infants are colonized with *C. difficile* at any one point in time, as are 10 to 25% of toddlers. Approximately 3% of healthy, asymptomatic adults are colonized with *C. difficile*, but the colonization prevalence of toxigenic *C. difficile* in hospitalized adults can be as high as 20%.[1] Although ambulatory adults are less likely than children to be colonized with *C. difficile*, clinical *C. difficile* infection is very uncommon in children, but the incidence increases with age, especially among people over age 60 years. For community-associated cases, new infections are mostly a result of the new acquisition of the organism followed by intestinal colonization. Most cases of health care–onset *C. difficile* infection are a result of a new acquisition of *C. difficile* after an antibiotic exposure, with a median of 3 to 7 days from the acquisition of *C. difficile* to the onset of infection.

The incidence and severity of *C. difficile* infection increased dramatically in the first decade of the 21st century, associated with a new predominant ribotype 027 strain, which was associated with dramatic outbreaks in North America and Europe. This strain, which is highly fluoroquinolone-resistant, produces a third toxin (binary toxin) and is readily transmissible in the health care setting. From 2011 to 2017, a 36% decline in the number of cases of health care–associated *C. difficile* infection (Chapter 261; from about 305,000 to about 195,000) have been associated with declines in the proportion of cases due to the 027 strain, from nearly 35% in 2011 to only 15% by 2017. This decline was likely due to improved antimicrobial stewardship and a focus on preventing *C. difficile* transmission in hospitals.[2,3] Similar declines have been noted in community-associated *C. difficile* infection cases due to the 027 strain over the same time period, but cases of community-associated *C. difficile* infection have remained constant at about 170,000 per year, apparently because of the ubiquity of *C. difficile* in the community and the stable or even increased prescribing of outpatient antibiotics.[4]

PATHOBIOLOGY

As a strict anaerobe, vegetative *C. difficile* cells die after exposure to oxygen. Its spores, however, can survive for months in the external environment and lead to colonization. The normal adult gut microbiota provides the first line of defense against *C. difficile* colonization and infection, and the decline in colonization from infancy to adolescence mirrors the maturation of the gut microbiome.[5] The metabolic activity of the healthy microbiome and competition for nutrients and binding sites determine whether *C. difficile* will colonize after an exposure and whether colonization will progress to clinical infection. For example, the microbiome converts primary bile salts, which are excreted into the bowel from the liver, into secondary bile salts that prevent *C. difficile*

ABSTRACT

Clostridial organisms are spore-forming, anaerobic, gram-positive bacilli that are found in a wide variety of environments, including soil, vegetation, and the gut of healthy animals. Their ability to produce spores allows them to survive for prolonged periods of time in challenging environments, including after exposure to many common household and hospital disinfectants. Another characteristic of clostridia that cause disease is their ability to produce toxins, and it is these toxins that often cause the hallmark features of clostridial infections. The clostridia with the greatest impact on human health today is *Clostridioides* (formerly *Clostridium*) *difficile*, which is the most common cause of health care–associated infections in the United States and is an associated complication in over 20,000 in-hospital deaths per year. By comparison, the incidence of other *Clostridioides* (e.g., *Clostridium tetani, C. botulinum*, and *C. perfringens*) has decreased due to improvements in hygiene and vaccinations, but diseases caused by those agents require prompt recognition and appropriate therapy to avoid preventable morbidity and mortality. Clostridia of emerging importance include *Paeniclostridium* (formerly *Clostridium) sordellii* (which is a cause of rapidly fatal infections in postpartum women, after medical abortions, in injection drug users, and after traumatic injuries), and *Clostridium novyi* (which is a cause of necrotizing infections in injection drug users).

spores from germinating and growing. Primary bile salts, which can have the opposite effect, are more prevalent when their conversion to secondary bile salts is reduced by the effect of antibiotics on the microbiome.

For *C. difficile* to cause infection, it must produce toxins A and B, both of which cause glucosylation of GTPase proteins, which then lead to cytoskeletal disruption and cell death. The specific binding receptors for toxins A and B are primarily localized to the human adult colon, thereby explaining the lack of *C. difficile* infection in infants and the rarity of small bowel involvement. After the colonic mucosal cells die, toxins A and B induce acute neutrophilic inflammation, which can be visualized as pseudomembranes on endoscopy. An important secondary line of defense appears to be production of antibodies against toxins A and B, in particular toxin B, to protect against recurrent *C. difficile* infection.[6]

CLINICAL MANIFESTATIONS

C. difficile may colonize the colon without symptoms. In the face of toxin production, the clinical symptoms of *C. difficile* infection range from mild diarrhea to profuse but usually nonbloody diarrhea. More severe infection may be associated with fever, cramps, leukocytosis, and hypoalbuminemia. Life-threatening pseudomembranous colitis is characterized by major fluid losses, hypotension, toxic megacolon, and/or systemic complications.

Leukocytosis occurs in about 50% of cases. Severe infection is usually defined as a white blood cell count of >15,000/μL accompanied by a serum creatinine level of 1.5 times or more of the baseline level. Severe complicated infection is commonly defined as an extremely high white blood count (>50,000/μL), often with lactic acidosis, hypotension, shock, ileus, and/or toxic megacolon.[7]

DIAGNOSIS

Unexplained diarrhea (typically defined as three or more loose or unformed stools in ≤24 hours), especially when associated with recent or current antibiotic exposure, should raise a suspicion of possible *C. difficile* infection. However, the clinical suspicion of *C. difficile* infection is often incorrect given the many possible causes of diarrhea, especially in patients who have multiple comorbid illnesses.

No single laboratory test is adequate for the reliable diagnosis of *C. difficile* infection, The most specific test to establish a *C. difficile* infection is the detection of toxins A and/or B in stool. The most commonly used laboratory method to detect *C. difficile* toxins is an enzyme immunoassay, but its sensitivity ranges from only about 50 to 80%. Nucleic acid amplification tests (NAATs), most commonly polymerase chain reaction (PCR) testing, have a sensitivity of 90 to 95% (compared with the "gold standard" of culture for a toxigenic strain) but can lead to the overdiagnosis of infection because the diarrhea may be due to other causes in patients, especially in older individuals who have been frequently hospitalized, who have harmless carriage of a toxigenic strain of *C. difficile*. Stool culture for *C. difficile* also lacks specificity, given the potential for *C. difficile* colonization as opposed to infection. Testing of stools for glutamate dehydrogenase, or "common antigen," is a rapid and sensitive screening test, but its specificity is only about 50%, so it requires confirmation with a toxin test.

Because of the limitations of each individual test, the optimal approach for the laboratory diagnosis of *C. difficile* infection is to use a combination of tests: PCR or glutamate dehydrogenase for screening, plus detection of free toxin in stools for confirmation. If patients have documented diarrhea (three or more loose or unformed stools in <24 hours) in the absence of other identifiable causes of diarrhea (e.g., laxative use and recent antibiotic use), PCR testing alone is usually adequate to make the diagnosis. For other patients, *C. difficile* infection can also be diagnosed by observing pseudomembranous colitis directly on sigmoidoscopy or colonoscopy, but this approach is best reserved for patients with a strong clinical suspicion of *C. difficile* infection despite negative laboratory testing.

Infectious diarrhea that persists for longer than 48 hours after hospital admission in an adult patient is almost always due to either *C. difficile* or norovirus (Chapter 350) infection. Common noninfectious causes of persistent diarrhea (Chapter 126) include laxatives, irritable bowel disease (Chapter 123), ischemic colitis (Chapter 129), and inflammatory bowel disease (Chapter 127). Of note, ischemic colitis can also cause pseudomembranes, which can be confused with *C. difficile* infection. For antibiotic-associated diarrhea with a negative *C. difficile* toxin assay, the cause is usually not identified. Since a negative toxin test result does not exclude a diagnosis of *C. difficile* infection, empiric treatment of *C. difficile* infection may still be considered in patients who have clinical symptoms highly suggestive of *C. difficile* infection after alternative diagnoses are excluded.

TREATMENT

When diarrhea is mild, the discontinuation of antibiotics and supportive care may be sufficient to effect cure. However, it is not possible to identify prospectively with confidence who will respond to such management, and most patients will require specific treatment.[8] Nevertheless, the offending antibiotic(s) should be discontinued because continuing them results in lower cure rates and higher rates of reinfection.

For patients with mild/moderate or severe *C. difficile* infection (variously defined as a white blood cell count >15,000/μL or a creatinine increase to >1.5-fold above baseline), fidaxomicin (200 mg orally twice a day for 10 days) is preferred over vancomycin (125 mg orally four times a day for 10 days) because it is equally efficacious for the acute infection and better for reducing the risk of recurrent infection.[A1] A clinical response typically occurs over several days (mean time to resolution of diarrhea is about 3 days). A failure to resolve by day 5 or 6 often indicates either that *C. difficile* is not the cause of the symptoms or, less commonly, that the disease has progressed too far. For fulminant *C. difficile* infection with an ileus, vancomycin (500 mg four times a day orally or by nasogastric tube) plus metronidazole (500 mg IV every 8 hours) is recommended, with vancomycin also potentially administered by enema. If symptoms progress despite this therapy, life-saving colectomy or a colon-sparing loop ileostomy should be considered before the white blood cell count reaches 50,000/μL or the lactate concentration exceeds 5.0 mmol/L.

Approximately 15% of patients treated with fidaxomicin (as compared with about 25% after treatment with vancomycin) have a recurrence of *C. difficile* infection within 4 weeks after treatment is completed, either because of a relapse (about 80% of cases) if *C. difficile* spores are not completely eradicated or reinfection (about 20% of cases) with a new strain. Patients with multiple recurrences of *C. difficile* infection are extremely difficult to treat and may benefit from consultation with an infectious disease specialist or gastroenterologist. For such recurrences, guidelines recommend fidaxomicin (standard dosing or dosing twice daily for 5 days and then every other day for 20 days under expert guidance).[A2] in preference to a standard course of vancomycin.[9] In patients who are receiving antibiotic treatment for primary or recurrent *C. difficile* infection, bezlotoxumab (a human monoclonal antibody against *C. difficile* toxin B infused at a dose of 10 mg per kilogram of body weight) is associated with a substantially lower rate of recurrent infection than placebo[10] and has a safety profile similar to that of placebo.[A3] Guidelines recommend using bezlotoxumab plus antibiotics for patients who have a recurrent *C. difficile* infection within 6 months.[11]

For three or more confirmed episodes of *C. difficile* infection, fecal microbiota transplantation, using fresh or frozen donor material administered via enema, colonoscopy, or oral capsules,[A4] is safe and efficacious to prevent recurrent *C. difficile* infection, with about a 70% cure rate.[A5,A6] Some data also support fecal microbiota transplantation over vancomycin for a first or second infection.[A7] Fecal transplantation is also superior to fidaxomicin for the treatment of recurrent *C. difficile* infection,[A8] and it has been shown to be safe for at least 3 to 4 years after transplantation.[12] RBX2660, a fecal microbiota-based product administered by enema,[A9] was recently approved by the U.S. Food and Drug Administration (FDA), and SER109, a capsule formulation, appears promising as well. Therapies under investigation to prevent recurrent *C. difficile* infection include oral administration of spores of a nontoxigenic *C. difficile* strain, which in one trial reduced *C. difficile* infection by about 75%.[A10]

PREVENTION

The key to preventing *C. difficile* infection focuses on preventing the transmission of *C. difficile* and to decrease the risk of infection if transmission occurs. The former is accomplished by contact precautions and the latter by antimicrobial stewardship (Chapter 261). Contact precautions involve placing patients with *C. difficile* infection into private rooms, when available, using dedicated equipment (e.g., isolation stethoscopes), and having health care personnel wear gowns and gloves whenever entering the patient's room. Proper and consistent use of gowns and gloves is key to preventing contamination of health care workers' hands. Alcohol hand hygiene products do not kill or remove *C. difficile* spores, but handwashing with soap and water removes, at best, 1 log of spores, even under experimental conditions where proper handwashing technique is ensured. Thorough cleaning of the environment is essential to eliminate spores. Although not necessary if thorough environmental cleaning is accomplished, a sporicidal agent (e.g., sodium hypochlorite) is often used as well. Preventing unnecessary antibiotic use and avoiding high-risk antibiotics (e.g., clindamycin, fluoroquinolones, and extended-spectrum cephalosporins) decreases the risk of colonization and infection by preserving the microbiome, and it is likely the most effective means at preventing *C. difficile* infection.

A concerning trend is the increasing concomitant use of oral vancomycin (125 mg daily) to prevent *C. difficile* infection while patients are receiving other antibiotics in the absence of well-done trials with adequate follow-up.[13] Oral vancomycin is highly disruptive to the microbiome and leads to a greater alteration of the microbiome and a higher risk for *C. difficile* infection once it is stopped. Probiotics are not effective for preventing *C. difficile* infection.

Research is ongoing to assess interventions aimed at asymptomatic *C. difficile* carriers. *C. difficile* toxoid vaccine is currently in phase III trials.

PROGNOSIS

The vast majority (about 80 to 85%) of symptomatic cases resolve after the implicated antibiotic is discontinued and a 10-day course of fidaxomicin or vancomycin is completed, but patients with refractory, fulminant disease eventually require colectomy. The incremented mortality rate of *C. difficile* infection for hospitalized patients may be as high as 7%, with the majority of fatalities occurring in patients over age 65 years, but the overall 30-day mortality appears to be about 15% because of patients' ages and comorbid conditions. For patients who have recurrences, the risk of death is 33% higher than for patients with a single episode.

CLOSTRIDIUM PERFRINGENS TYPE A DIARRHEA

C. perfringens type A causes food poisoning after the ingestion of food, usually meat, that is heavily contaminated with enterotoxin-producing strains. Storage at room temperature rather than refrigeration is typically the underlying cause. The ingested vegetative bacteria sporulate and produce enterotoxin in the small intestine. After an incubation period of 7 to 15 hours, patients develop usually mild and self-limited diarrhea and abdominal pain.

In hospitalized or institutionalized patients, this bacterium can cause severe and protracted infectious diarrhea, often in the setting of prior or concomitant use of antibiotics.[14] In institutionalized mentally ill patients, use of antidiarrheal agents has been associated with necrotizing colitis. Diagnostic confirmation relies on detection of *C. perfringens* enterotoxin in the stool or a count of 10^6 or more *C. perfringens* organisms per gram of stool within 48 hours after the onset of a typical illness.

TREATMENT

Most cases are self-limited and do not need treatment. Metronidazole (e.g., 500 mg four times daily for 7 to 14 days) is recommended for patients who have protracted diarrhea. As with *C. difficile* infection, however, diarrhea may recur after successful treatment.

CLOSTRIDIUM PERFRINGENS TYPE C ENTERITIS

C. perfringens type C enteritis, also called enteritis necroticans, is a necrotizing proximal small intestinal infection caused by strains of *C. perfringens* that produce β-toxin. Enteritis necroticans can occur sporadically or in outbreaks, most often in developing countries, where it primarily affects children with severe protein malnutrition (Chapter 197). Enteritis necroticans also occurs sporadically in the developed world, particularly among patients with diabetes. Histopathologic findings include deep small intestinal necrosis with vascular necrosis and hemorrhage in the lamina propria.

Affected patients usually develop severe abdominal pain 12 hours to several days after eating contaminated food. Vomiting and bloody diarrhea are frequent, and the abdomen becomes distended with thickened bowel loops. The diagnosis is usually clinical. Culture to identify specific β-toxin–producing strains of *C. perfringens* remains a research tool.

TREATMENT AND PROGNOSIS

Treatment is primarily supportive, including nasogastric suction and rehydration. Surgical resection of the infected bowel is often required in patients who do not initially respond to supportive measures. Empirical antibiotics (e.g., penicillin, chloramphenicol, metronidazole) are typically prescribed under expert guidance, but their efficacy is unknown. Prognosis, which depends on the extent of disease and the availability of surgery, ranges from spontaneous recovery to death.

NECROTIZING CLOSTRIDIAL TISSUE INFECTION

CLOSTRIDIAL MYONECROSIS (GAS GANGRENE)

Clostridial myonecrosis, or gas gangrene, is a life-threatening infection that can be cause by several *Clostridium* species. Traumatic gas gangrene is typically caused by *Clostridium perfringens*. *Clostridium septicum* is associated with spontaneous gangrene, believed to be related to translocation of the bacterium from the gut associated with an occult neoplasm.

EPIDEMIOLOGY

Traumatic gas gangrene is typically seen after traumatic injury (e.g., motor vehicle accidents, gunshot and knife wounds, crush injuries, and subcutaneous injections), particularly if treatment is delayed. The vast majority of post-traumatic cases are due to *C. perfringens*, but cases also can be associated with *C. septicum*, *C. novyi*, *C. histolyticum*, *C. bifermentans*, *C. tertium*, and *C. fallax*. Approximately 30% of cases occur after bowel or biliary tract surgery because of translocation of bacteria across the gut wall, often in association with adenocarcinoma of the colon. Infection can also occur in the setting of neutropenic enterocolitis after intense chemotherapy for treatment of acute leukemia.

PATHOBIOLOGY

C. perfringens is found worldwide in soil and feces. Deep penetrating trauma can introduce spores and foreign bodies, thereby creating conditions conducive to an anaerobic environment with a low-oxidation-reduction potential and acidic pH, which support germination of spores and growth of clostridial organisms. *C. perfringens* is able to produce at least 12 toxins, but α-toxin and θ-toxin are believed to be the most important[15] for both the widespread tissue necrosis and the characteristic absence of an inflammatory tissue response. These toxins cause a rapid, irreversible ischemic muscle necrosis due to formation of intravascular aggregates of platelets and neutrophils. These aggregations then impede translocation of inflammatory cells from the vasculature to the site of infection. These toxins also contribute to shock by depressing myocardial contractility and reducing vascular resistance.

The mechanism that facilitates the translocation of *C. septicum* across the gut wall in the presence of a malignancy is unknown. *C. septicum* produces an α-toxin, unrelated to the *C. perfringens* α-toxin, that causes cell death and changes in microvascular profusion.

CLINICAL MANIFESTATIONS

Traumatic clostridial myonecrosis usually presents with sudden onset of severe pain at the site of injury.[16] The mean incubation period is less than 24 hours, but onset can be several weeks after the injury. The infected area initially may appear pale but rapidly progresses to a bronze appearance, followed by purple or red discoloration and then bullae formation. The skin becomes tense and exquisitely tender. The drainage is described as having a "dish water" appearance and smells "foul-sweet." Refractory hypotension unresponsive to fluid resuscitation is common. Approximately 15% of patients are bacteremic, sometimes complicated by brisk intravascular hemolysis. Renal failure and multisystem organ failure typically ensue. Postoperative gas gangrene should be suspected if a surgical site infection develops less than 24 hours after bowel or biliary surgery.

Spontaneous clostridial myonecrosis presents with abrupt onset of severe muscle pain. Infection progresses rapidly with development of edema and bullae. This syndrome is associated with colonic neoplasms (both known and occult), neutropenic enterocolitis, leukemia, and inflammatory bowel disease.

DIAGNOSIS

Patients typically present with severe pain at the site of infection with rapid progression from edema to discoloration to the formation of bullae. Patients typically have signs and symptoms of systemic toxicity. Gas in the tissue may be evident by crepitation on palpation or on imaging, but surgical intervention for suspected infection should not be delayed to obtain imaging to confirm the presence of gas. Drainage may be present or aspirated, and Gram stain characteristically reveals abundant gram-positive bacilli without inflammatory cells. Nucleic acid testing has too low a sensitivity to be depended upon.[17] Surgical exploration typically demonstrates muscle that does not bleed or contract when stimulated. Muscle tissue is grossly edematous and may have reddish-blue to black discoloration.

TREATMENT

Prompt recognition, surgical inspection, and aggressive (and often extensive) surgical debridement are necessary to improve survival. Initial treatment while awaiting antimicrobial susceptibility testing should be a combination of penicillin (or a β-lactam/β-lactamase combination or carbapenems for polymicrobial infections) and clindamycin under expert guidance. *C. perfringens* is more likely to be resistant to clindamycin, but clindamycin is preferred for susceptible isolates because it reduces the production of toxin. Other antibiotics with activity against susceptible strains include metronidazole, tetracyclines, and chloramphenicol.

PREVENTION

Prolonged application of tourniquets should be avoided, if possible, to maintain vascular integrity. Prompt surgical exploration of traumatic wounds with debridement of devitalized tissue; removal of foreign bodies, dirt, and debris; and drainage of hematomas are key to preventing traumatic gas gangrene.

PROGNOSIS

In one series, all patients who died had shock at the time of diagnosis, and 40% of patients with shock died compared with 20% overall. Other factors associated with a worse prognosis include advanced age, leukopenia, and hemolysis. Factors associated with a better prognosis include younger age, single limb involvement, and early aggressive surgical debridement.

PAENICLOSTRIDIUM SORDELLII

P. sordellii is a rare, gram-positive, anaerobic, spore-forming rod. It produces several toxins, some of which are antigenically similar to *C. difficile* toxins A and B, which can lead to overwhelming sepsis, necrotizing infections, and death, mainly in postpartum women, injection drug users, and survivors of trauma.

EPIDEMIOLOGY

P. sordellii can be found worldwide in sewage, soil, the intestinal tract of animals, the intestinal tracts of about 0.5% of humans, and the vaginal tracts of 0.5 to 10% of women. Clinical infection can occur after traumatic wounds, childbirth, medical or spontaneous abortion, and injection of drugs into the skin or muscle ("popping").

PATHOBIOLOGY

The main *P. sordellii* toxins are believed to be the lethal toxin and the hemorrhagic toxin, both of which are encoded by genes that are located on plasmids, which not all *P. sordellii* carry. These toxins, which are antigenically similar to *C. difficile* toxins A and B, impair cytoskeletal organization and can cause massive capillary leakage, thereby leading to progressive edema. They also can cause toxic shock even with minimal signs of local infection.

CLINICAL MANIFESTATIONS

After childbirth or after (spontaneous, medical, or surgical) abortion, patients typically present within a week with nausea, vomiting, diarrhea, tachycardia, and hypotension in the absence of fever. The uterus is often, but not always, tender on examination and enlarged on imaging. Capillary leak results in vascular collapse, toxic shock, diffuse edema, pleural and peritoneal effusions, and hemoconcentration with a hematocrit level as high as 80%. The white blood cell count is typically >50,000 cells/μL and can exceed 200,000 cells/μL.

P. sordellii is associated with necrotizing skin and soft tissue infections after trauma and with the injection of drugs into the skin or soft tissue, especially with the use of black tar heroin (a freebase form of heroin that is dark in color and sticky like tar or hard like coal due to crude processing methods that leave behind impurities). Patients typically present with necrotizing fasciitis at the site of injection, often with hypotension. Infections, which are typically polymicrobial, may occur in clusters of drug users because of shared use of a contaminated drug.

DIAGNOSIS

The diagnosis of *P. sordellii* infection can be challenging due to lack of specific symptoms before overwhelming infection leads to an almost universally fatal outcome. Infection should be suspected in a woman who presents within days of childbirth or an abortion with nausea, vomiting, or diarrhea with leukocytosis. PCR of material from the site of infection is the test of choice.

TREATMENT AND PROGNOSIS

Aggressive supportive care and surgical removal of infected tissue are paramount. Initial antimicrobial therapy should be broad spectrum and cover gram-positive, gram-negative, and anaerobic organisms since infections due to *P. sordellii* are frequently polymicrobial. Due to the infrequency of infections caused by *P. sordellii*, definitive treatment has not been identified, but antibiotics with in vitro activity against *P. sordellii* include β-lactams with anaerobic activity, carbapenems, clindamycin, metronidazole, and chloramphenicol given under expert supervision. Antitoxin is not currently available. Despite treatment, reported mortality is 100% with infection after childbirth and abortion and 50% with injection drug use.

CLOSTRIDIUM NOVYI INFECTION IN INJECTION DRUG USERS

C. novyi is found in soil and feces with a worldwide distribution. Some strains are infected with a phage that has the gene for α-toxin, a large clostridial toxin. As with other large clostridial toxins produced by *C. difficile* and *P. sordellii*, it glucosylates cellular GTPase proteins, thereby leading to the dysfuction of the actin cytoskeleton and cell death. Clusters resulted in 295 cases of infection among people who injected heroin into skin and muscle ("popping") in the United Kingdom from 2000 to 2009. Infections are associated with injection site edema, necrotizing fasciitis, generalized edema, and pleural effusions. Infections tended to be polymicrobial. Treatment involves surgical debridement and broad-spectrum antibiotics under expert supervision.

NEUROTOXIC CLOSTRIDIAL INFECTIONS

BOTULISM

DEFINITION

Botulism, which is caused by the action of botulinum toxin, is characterized by a descending flaccid paralysis.

The Pathogen

C. botulinum, which is a gram-positive, spore-forming obligate anaerobe, is widely distributed in agricultural products, soil, and marine environments. Each strain produces one of eight toxins designated by the letters A to H. The seven known botulinum neurotoxin–producing species of *Clostridium* include *C. baratii, C. argentinense, C. butyricum*, and subtypes of these species. All these neurotoxins produce the same syndrome; the usual causes of disease in humans are types A, B, and E, with rare cases caused by type F and the other types.

EPIDEMIOLOGY AND PATHOBIOLOGY

Botulism in humans is generally foodborne, wound-related, or infantile. Rarely, botulism may be iatrogenic when too much botulinum toxin is injected for cosmetic reasons or the injection is inadvertently systemic. Botulinum toxin is also a potential bioterrorism agent (Chapter 19) if inhaled or ingested.

Worldwide, foodborne botulism is most common, most often due to type A toxin, but with marked geographical differences. In the United States, the Centers for Disease Control and Prevention (CDC) has recorded hundreds of outbreaks of foodborne botulism, usually from home-canned vegetables or fermented foods, occasionally from commercially preserved and restaurant-prepared foods.[18] However, most cases are sporadic, with Alaska accounting for about one-third of cases, usually type E, related to fermented fish and marine mammals prepared and consumed by native Alaskans. In Europe, meat and meat products are more frequently implicated, with type B toxin predominating. In China, vegetable products contaminated with type A toxin predominate.

Infantile botulism is caused by the intestinal production of botulinum toxin, usually type A or type B, after presumed ingestion of spores and colonization of the colon. Contaminated honey is one source, but most often the origin is never identified. The symptoms usually start as constipation followed by poor feeding, weak cry, lethargy, and generalized weakness. This form of botulism rarely occurs in adults but has been reported in patients with anatomic or functional gut abnormalities, such as blind pouches secondary to a side-to-side intestinal anastomosis.

Wound botulism, which is the least common form, occurs sporadically in traumatic wounds that have been contaminated by spores in soil. Outbreaks have been described in black tar heroin users who inject the drug intramuscularly or subcutaneously. Most cases are due to type A or type B toxin.

Botulinum toxin is considered a prime potential bioterror agent (Chapter 19). Potential distribution methods include contamination of food, water, or commercial beverages, as well as aerosolization in densely populated locales. A single release of aerosolized toxin could potentially incapacitate or kill 10% of the population within a 0.5-km radius.

Iatrogenic botulism is an uncommon but growing concern because of the increasing use of botulinum toxin for cosmetic or therapeutic purposes. Cosmetic doses are far too low to cause systemic disease, but unlicensed products with high concentrations may cause systemic symptoms. Higher doses used for movement disorders (Chapter 379) have occasionally caused systemic botulism.

The flaccid paralysis of botulism is due to blockade of the transmission of acetylcholine across the neuromuscular junction of presynaptic motor neurons

that innervate muscles. For a 70-kg human, the estimated lethal dose of purified botulinum toxin A is 0.09 to 0.15 μg when given intravenously, 0.8 to 0.9 μg when inhaled, and 70 μg when given orally.

CLINICAL MANIFESTATIONS

Symptoms typically develop 10 hours to 5 days after consuming a suspect food, such as preserved or home-canned foods. The clinical presentation begins with symmetrical palsies of cranial nerves III, IV, and VI with blurred vision and diplopia.[19] If cranial nerves VII or IX are affected, patients develop expressionless facies with dysphagia, dysarthria, and, rarely, dysphonia. Patients next develop a symmetrical descending flaccid paralysis, with potential involvement of respiratory muscles. Nausea, vomiting, abdominal pain, and diarrhea are common early in the illness, and constipation may occur as paralysis develops. Progression over hours or days and the extent of disease are highly variable, with symptoms sometimes restricted to a few cranial nerves but sometimes progressing to complete paralysis of all voluntary muscles.

Neurologic examination shows ptosis, dilated pupils with a sluggish reaction, bilateral cranial nerve VI paresis, and a diminished gag reflex, followed by descending motor neuron involvement. Deep tendon reflexes are diminished or absent. Cognition is often retained, and vital signs are normal.

DIAGNOSIS

The clinical presentation of an acute flaccid paralysis involving the cranial nerves, particularly including bilateral dysfunction of cranial nerve VI, should prompt the inclusion of botulism in the differential diagnosis, especially if more than one person is affected. The generalized weakness and descending paralysis seen in botulism are in contrast to the ascending paralysis of Guillain-Barré syndrome (Chapter 388). In the absence of a suspect food, another source, such as potentially infected wounds and drug injection sites, should be sought. Bioterrorism-associated botulism could unfortunately be associated with large numbers of cases that may not have a typical food or wound source.

Botulinum toxin can be detected by specialist (public health) laboratories in food or in serum, stool, or gastric contents collected before the administration of antitoxin. Culture of stool and suspect food or wounds is also indicated. About one-third of adult patients with clinical evidence of foodborne botulism have detectable toxin in sera and/or in stool, and the bacterium can be recovered from stool in approximately two-thirds of cases. For wound botulism, recovery of *C. botulinum* from wound cultures or detection of toxin in serum is diagnostic.

The differential diagnosis includes myasthenia gravis (Chapter 390), Guillain-Barré syndrome (Chapter 388), tick paralysis (Chapter 383), cerebrovascular accident (Chapters 376 and 377), trichinosis (Chapter 327), Eaton-Lambert syndrome (Chapter 390), hypocalcemia (Chapter 227), hypermagnesemia (Chapter 105), organophosphate poisoning (Chapter 96), atropine poisoning (Chapter 96), and paralytic poisoning by shellfish or puffer fish (Chapter 96). On electromyography, findings are similar in both botulism and Eaton-Lambert syndrome. Cerebrospinal fluid analysis and cranial imaging are normal in botulism.

TREATMENT

Clinicians who suspect botulism should contact their state health department and can obtain expert advice from the CDC Emergency Operations Center (telephone: 770-488-7100). Similar public health agencies should be contacted in other countries.

Early administration of antitoxin is key and should not be delayed until microbiologic results are available.[20] Antitoxin does not reverse paralysis or neutralize toxin already bound to nerve endings, but it prevents progression by neutralizing circulating unbound toxin.

The standard treatment of adults is heptavalent botulinum antitoxin obtained through a CDC-sponsored FDA investigational new drug protocol. Heptavalent botulinum antitoxin contains equine-derived antibodies to all seven known botulinum toxin types (A to G). Since the antitoxin is derived from horses, hypersensitivity reactions can occur. BabyBIG (botulism immune globulin), which is a human-derived treatment for infantile botulism types A and B, is available through the California Infant Botulism Treatment and Prevention Program.

Gastric lavage, cathartics, or enemas can be used early during management to remove gastrointestinal tract toxin. Because of the risk of respiratory failure, which occurs in about 20% of cases in foodborne disease and about 60% of cases of infantile botulism, patients' respiratory status must be monitored carefully. Other supportive care commonly includes enteral or parenteral feeding (Chapter 198) and positioning in the reverse Trendelenburg position. Antibiotic treatment is unnecessary, except for wound botulism.

PREVENTION

Destroying spores in the original food source by appropriate heating, inhibiting germination, or denaturing preformed toxin (also by heating) is the basis of prevention of foodborne disease.

PROGNOSIS

Death is usually caused by respiratory failure, but the case-fatality rate has decreased from 60 to 70% for untreated botulism to 3 to 5% with treatment. In the United States, infantile botulism has a mortality rate of less than 1%. Patients who survive usually recover completely.

TETANUS

DEFINITION

Tetanus is characterized by generalized rigidity and convulsive spasm of skeletal muscles caused by a neurotoxin produced by *C. tetani* at the site of injury.[21]

The Pathogen

C. tetani is a gram-positive, anaerobic, slender, motile bacillus whose spores have a characteristic shape resembling a drumstick or tennis racket. The vegetative bacteria produce tetanospasmin, which is a protein neurotoxin whose heavy chain binds neuronal cells and whose light chain blocks the release of neurotransmitters.

EPIDEMIOLOGY

C. tetani can be found in up to a quarter of soil samples, particularly when animal manures have been applied. *C. tetani* can also be present in the feces of a variety of domestic and farm animals and poultry.

Clinical tetanus is most common in warm climates and in highly cultivated rural areas of developing countries, where an estimated 60,000 neonatal cases occur annually in low-income countries.[22] Diabetes, a history of immunosuppression, and intravenous drug use are risk factors for tetanus. An average of about 30 cases of tetanus are reported annually in the United States.

PATHOBIOLOGY

Tetanus neurotoxin, which is sometimes referred to as tetanospasmin, is lethal in humans at a dose of 2.5 ng/kg, thereby placing it among the most potent known microbial toxins. Clinical tetanus usually occurs following *C. tetani* contamination of a wound in which the oxygen tension is low because oxygen is toxic to *C. tetani*. *C. tetani* wound contamination is usually via trauma or surgery or at a drug injection site, burn, skin ulcer, or immature umbilical cord. In a low-oxygen setting, spores can germinate and produce tetanospasmin, which binds the peripheral nerve terminals and is then transported (approximately 75 to 250 mm/day) intra-axonally within membrane-bound vesicles to spinal neurons. The light chain passes to the presynaptic terminals, where it blocks the release of neurotransmitters by inhibitory afferent motor neurons. Loss of inhibitory action results in sustained muscle contraction. Toxin binding is irreversible, so recovery depends on the growth of new axon terminals.

CLINICAL MANIFESTATIONS

After a 3- to 21-day (mean: 8 days) incubation period, depending primarily on the distance between the site of injury and the central nervous system, generalized tetanus, which is the most common manifestation, occurs in 80 to 90% of reported cases in the United States. Shorter incubation periods are generally associated with more severe symptoms. Generalized tetanus is characterized by a persistent tonic spasm with short intermittent exacerbations, invariably involving the neck and jaw. This trismus (lockjaw), which is the initial complaint in about three-quarters of cases, often brings patients to a dentist or oral surgeon. Other early symptoms and signs include irritability, restlessness, diaphoresis, and dysphagia with hydrophobia and drooling. Persistent spasms of the paraspinous muscles may cause opisthotonos. As the disease progresses, all muscles contract, with larger muscles dominating smaller muscles. Noise or tactile stimuli may precipitate spasms and generalized convulsions. Involvement of the autonomic nervous system may result in laryngeal spasm, labile blood pressure, cardiac arrhythmias, profound diaphoresis, hyperthermia, rhabdomyolysis, and urinary retention. Complications include dehydration, bacterial infections, fractures from sustained contractions, and pulmonary emboli. However, patients typically remain lucid and afebrile, unless they have complicating infections.

Local tetanus is rare, shows considerable variation in severity, and is characterized by persistent muscle contractions or spasms in the extremity associated with a contaminated wound. In more severe cases, local painful spasms progress to generalized tetanus. Cephalic tetanus is also rare and generally follows a head injury or *C. tetani* infection of the middle ear. After a 1- or 2-day period,

clinical symptoms consist of isolated or combined dysfunction of the cranial motor nerves, most frequently cranial nerve VII. Dysfunction may remain localized or progress to generalized tetanus, and survival rates are poor.

Neonatal tetanus is an age-specific presentation of generalized tetanus, usually when *C. tetani* contaminates the umbilical stump soon after birth. It occurs primarily in underdeveloped countries, where it accounts for up to half of all neonatal deaths.

DIAGNOSIS

The diagnosis of tetanus is usually clinical, and *C. tetani* is recovered from wound or tissue culture in only about one-third of cases. Cerebrospinal fluid analysis is entirely normal. The differential diagnosis includes dystonic reactions (Chapter 379), seizure disorders (Chapter 372), hypocalcemic or alkalotic tetany (Chapter 227), alcohol withdrawal (Chapter 364), and strychnine poisoning (Chapter 96). Although dystonic reactions may resemble tetanus, they can be distinguished from tetanus by their rapid response to anticholinergic agents (Chapter 96). Strychnine poisoning can be diagnosed by detecting it in blood or urine.

TREATMENT

Patients with tetanus require intensive care with meticulous respiratory support, control of muscle spasms, control of autonomic nervous system dysfunction, passive and active immunization, antibiotics, and surgical debridement. The severity of disease may be attenuated by partial immunity, so some patients have mild disease, whereas other patients have more severe disease.

Supportive Care

Many patients require endotracheal intubation, benzodiazepine sedation, and neuromuscular blockade. A tracheostomy should be placed if the endotracheal tube causes spasms. A feeding tube is usually required for nutritional support.

Benzodiazepines, usually diazepam given intravenously in 5-mg increments, are used to control spasms and provide sedation. Very high doses may be required before symptoms resolve, at which time benzodiazepines should be tapered over at least 2 weeks to prevent withdrawal. If benzodiazepines cannot control spasms, neuromuscular blockade with vecuronium (6 to 8 mg/hour) is required.

Autonomic Nervous System Dysfunction

Autonomic nervous system dysfunction, which generally reflects the excessive release of catecholamines, is usually treated with labetalol (0.25 to 1.0 mg/minute) to control blood pressure. Hypotension may require norepinephrine (Chapter 92). Bradycardia may require a pacemaker (Chapter 51).

Specific Care

Human tetanus immunoglobulin (a single dose of 500 IU intramuscularly) should be administered as soon as possible to neutralize toxin that has not entered neurons. Pooled intravenous immunoglobulin and equine tetanus immunoglobulin are alternatives, but they should not be used if human tetanus immunoglobulin is available.

Passive immunization should be accompanied by active immunization with a standard three-dose schedule of tetanus toxoid at a site separate from where immunoglobulin is administered. Patients also should be given metronidazole (2 g/day intravenously for 7 to 10 days). Any wounds should be debrided and cleaned.

PREVENTION

Tetanus toxoid vaccination (Chapter 15) is extremely effective, and nearly all cases of tetanus occur in unimmunized or inadequately immunized individuals. Protective levels of serum tetanus antitoxin persist for at least 10 years in persons who complete the primary series. The incremental benefit of routine booster shots for preventing tetanus appears to be very small, at best,[23] but Td (tetanus and diphtheria toxoids adsorbed for adult use) is recommended every 10 years (Chapter 15). All adults aged 19 years and older who have not yet received a dose of Tdap (tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis) should receive a single dose regardless of the interval since the last Td to protect against pertussis.[24]

Prevention of tetanus after injury (Table 271-1) requires optimal wound management, assurance of adequate immunity with a tetanus booster if indicated, and consideration of antibiotic prophylaxis. Debridement or surgery may be required to remove necrotic tissue, purulent collections, or foreign bodies that promote the low-oxygen conditions necessary for tentaus spores to germinate. Passive immunization with tetanus immune globulin is recommended only for patients who have not had adequate prior immunization and whose wound is at high risk of contamination with tetanus based on the interval since the injury, the presence of devitalized tissue, the depth of the injury, or the prlonged presence of a foreign body. Point-of-care testing for tetanus immunity is a potential method for reducing unnecessary re-immunization.[25]

TABLE 271-1 GUIDE TO TETANUS PROPHYLAXIS IN ROUTINE WOUND MANAGEMENT

HISTORY OF ADSORBED TETANUS TOXOID (NO. OF DOSES)	*CLEAN MINOR WOUNDS*		*ALL OTHER WOUNDS**	
	Tdap OR Td†	TIG‡	Tdap OR Td†	TIG‡
<3 or unknown	Yes	No	Yes	Yes
≥3	No§	No	No¶	No

*Such as (but not limited to) wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

†For children younger than 7 years, DTaP (pediatric diphtheria–tetanus toxoid plus acellular pertussis vaccine) is recommended; if pertussis vaccine is contraindicated, DT (pediatric diphtheria–tetanus toxoid) is given. For persons aged 7 to 9 years or 65 years or older, Td (adult tetanus–diphtheria toxoid) is recommended. For persons 10 to 64 years, Tdap (adult tetanus–diphtheria toxoid plus acellular pertussis vaccine) is preferred to Td if the patient has never received Tdap and has no contraindication to pertussis vaccine. For persons 7 years and older, if Tdap is not available or not indicated because of age, Td is preferred to TT (tetanus toxoid alone). Note that pediatric formulations (DT and DTaP) contain an amount of tetanus toxoid similar to that of adult Td, but they contain three to four times as much diphtheria toxoid. DTaP and Tdap vaccines do not contain thimerosal as a preservative.

‡TIG is human tetanus immune globulin. Equine tetanus antitoxin should be used when TIG is not available.

§Yes, if more than 10 years since the last dose.

¶Yes, if more than 5 years since the last dose.

From Gerding DN, Johnson S. Clostridial infections. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. New York: Elsevier Health Services; 2019:1890-1897.

Penicillin (500 mg every 6 hours) and metronidazole (500 mg every 6 to 8 hours) for 7 days may be given, but immunization and wound cleansing are more important to prevent tetanus.

PROGNOSIS

Even with antitoxin therapy, symptoms persist usually for 3 to 4 weeks because of the time required for intra-axonal toxin transport, so patients with moderate or severe generalized tetanus usually require hospital treatment for 3 to 6 weeks. The overall mortality rate with generalized tetanus is 20 to 25% despite optimal medical management. Mortality rates are low in partially immunized patients but about 50 to 60% in unimmunized patients despite expert care.[26] The highest mortality rates are at the extremes of age, usually from pneumonia. Patients who recover usually do so completely. Local tetanus has an excellent prognosis, with about a 1% mortality rate, but survival is poor for cephalic tetanus, with a 15 to 30% mortality rate.

272 GRAM-POSITIVE ROD INFECTIONS

ROSE KIM, HEATHER CLAUSS, AND ANNETTE C. REBOLI

INFECTIONS CAUSED BY *BACILLUS ANTHRACIS* AND OTHER *BACILLUS* SPECIES

DEFINITION

The genus *Bacillus* includes several species that are closely related phylogenetically. The *Bacillus cereus* group includes *Bacillus anthracis*, which is the causative agent of anthrax; *Bacillus cereus*, which causes food poisoning as well as localized and systemic infections; and *Bacillus thuringiensis*, an insect pathogen that causes eye infections and infections in immunocompromised persons.[1] Other *Bacillus* species that have caused infections in humans include *circulans, licheniformis, megaterium, pumilus, sphaericus*, and *subtilis* (Table 272-1).

The Pathogen

Bacillus species are large, aerobic or facultatively anaerobic, spore-forming, gram-positive bacilli (Fig. 272-1). The major pathogenic species of the *B. cereus* group have plasmids that carry genes for toxin proteins.

EPIDEMIOLOGY

Bacillus species are endemic in soil and water and are found worldwide. Their spores are extremely hardy and are resistant to heat and drying, so they can persist in a dormant state for prolonged periods of time. Spores may survive in soil for decades and may also survive for several years in the interior of buildings where they are protected from ultraviolet light. Spores have also been isolated from foodstuffs, insects, and plants. Persistence of spores in the soil is influenced by a variety of environmental conditions such as higher temperature, low soil moisture content, drought following a period of high annual rainfall, and alkaline pH.

Bacillus anthracis

Anthrax occurs most commonly in Africa, India, the Middle East, Southeast Asia, and parts of Central and South America. Anthrax is enzootic in sub-Saharan Africa, where cases occur in wildlife and domestic animals that ingest or inhale *B. anthracis* spores from the soil while grazing. Cases may be sporadic or occur as part of an outbreak. Human cases in Africa outnumber human cases in most of the rest of the world. In Europe and North America, animal cases are sporadic and human cases are rare. Even a single case in a nonendemic area should generate concern for an act of bioterrorism (Chapter 19).

Human cases of anthrax are usually associated with exposure to infected animals or their products. Cases can occur sporadically or be associated with outbreaks. Implicated products include meat, bone, wool (wool sorters disease), hair, hides, and items made from these materials. Transmission from flies has been reported to cause cutaneous infection.

Inhalational anthrax occurs from breathing in spores from contaminated animal products or after intentional release of spores during an act of bioterrorism. Gastrointestinal anthrax is acquired by ingesting spores or vegetative forms in the meat of infected animals or from contaminated water. Injectional anthrax infections have been reported in injection drug users who used heroin contaminated with anthrax spores.[2]

Several outbreaks have been reported. In a 1979 outbreak in Sverdlovsk, Russia, 70 cases of confirmed inhalational anthrax occurred after an accidental release of spores from a military facility. In the largest human outbreak, approximately 10,000 cases, almost all of which were cutaneous, and 182 deaths occurred over a 6-year period from 1979 through 1985 in Zimbabwe. In 2001, letters containing anthrax spores were sent via the U.S. Postal Service to recipients in Florida, New York City, and Washington, D.C. Ultimately, 22 people were infected, with 11 cutaneous infections, 11 inhalational infections, and 5 deaths. Approximately 10,000 U.S. citizens received postexposure antibiotic prophylaxis to contain the outbreak.

Bacillus cereus

The foods most commonly associated with *B. cereus* food poisoning include meats, vegetables, and sauces. The emetic form of *B. cereus* food poisoning is frequently associated with starchy foods such as rice, especially fried rice, and potato salad. Improper storage and handling of food is the most likely cause. Contaminated rice has often been stored at room temperature to preserve its texture and then been reheated. Reheating may eliminate the organism and the diarrheal toxin but not the emetic toxin.

B. cereus, which is the most frequent bacteria that contaminates breast milk,[3] can cause severe infection in very low-birthweight newborns. *B. cereus* can contaminate the product during collection, storage, or delivery. Cases of keratitis have been linked to contamination of contact lenses.

TABLE 272-1 NON-ANTHRAX *BACILLUS* SPECIES ASSOCIATED WITH HUMAN DISEASE

SITE OF INFECTION	PATHOGEN	CLINICAL SYNDROME
Blood stream	*B. cereus* *B. circulans* *B. licheniformis* *B. megaterium* *B. pumilus* *B. sphaericus* *B. subtilis*	Bacteremia Catheter-related sepsis
Bone/joints	*B. cereus* *B. alvei*	Osteomyelitis Septic arthritis
Brain/meninges	*B. cereus* *B. circulans* *B. megaterium* *B. subtilis* *B. licheniformis* *B. pumilus* *B. sphaericus*	Meningoencephalitis Meningitis CSF shunt infections Meningitis post-CSF leak
Eye	*B. cereus* *B. circulans* *B. thuringiensis*	Endophthalmitis Keratitis Corneal ulcers
Gastrointestinal	*B. cereus* *B. licheniformis* *B. subtilis* *B. pumilus*	Emetic food poisoning Diarrheal food poisoning
Heart	*B. cereus* *B. circulans* *B. subtilis*	Endocarditis

ABSTRACT

Gram-positive bacillary organisms, including *Bacillus, Corynebacteria, Erysipelothrix*, and *Listeria*, are rod-shaped bacteria that are ubiquitous and commonly found in soil and water. Depending upon the genus, they may be spore-forming or non-sporulating. As a group, they are potentially serious but relatively rare causes of disease in humans, and sometimes they are erroneously dismissed as laboratory contaminants. Many cause zoonotic infections.

KEYWORDS

Bacillus anthracis
anthrax
Bacillus cereus
Corynebacterium diphtheriae
diphtheria
Listeria monocytogenes
listeriosis
Erysipelothrix
Erysipeloid infection

PATHOBIOLOGY

Bacillus anthracis

Cutaneous anthrax occurs when *B. anthracis* spores are introduced through microscopic or gross breaks in the skin, and injectional anthrax occurs via direct injection through intact skin. In classic cutaneous anthrax, a pustule forms at the inoculation site and ulcerates as the result of coagulation necrosis. Extensive edema surrounds the lesion. The organism multiplies locally and may spread to the blood stream or other organs via the lymphatics. The site of injectional anthrax has extensive edema but lacks the other findings of cutaneous anthrax.

Upon inhalation, *B. anthracis* spores are transported by alveolar macrophages and dendritic cells to regional lymph nodes. The spores germinate in blood and tissue. Following germination, vegetative cells produce an antiphagocytic capsule[4] and anthrax toxin proteins, which are important virulence factors. Anthrax toxin consists of three proteins: protective antigen, edema factor, and lethal factor. These toxins neutralize the innate and adaptive immune systems to cause fatal disease. The capsule not only prevents phagocytosis but also enhances cytotoxicity and induces production of cytokines. Pulmonary infiltrates, which are seen radiographically in approximately a third of cases, are areas of pulmonary edema and hyaline membrane formation, not bacterial pneumonia. Pleural effusions are caused by blockage of normal lymphatic flow in the mediastinum.

Gastrointestinal anthrax may be classified as primary or secondary. Primary gastrointestinal anthrax occurs after the ingestion of meat from an animal infected with anthrax, whereas secondary gastrointestinal anthrax results from *B. anthracis* bacteremia. Spores invade the gastrointestinal mucosa, where they cause necrosis and ulceration that may lead to hemorrhage. Spores are then transported to mesenteric lymph nodes where they replicate and cause bacteremia.

Meningitis, which may occur as a complication of any form of anthrax, results from hematogenous seeding of the meninges. The meninges are edematous and hemorrhagic. Diffuse cerebral arteritis may occur.

Bacillus cereus

The pathogenic potential of *B. cereus* is highly variable and is based on a number of virulence factors. Enterotoxins ingested with contaminated foods cause diarrhea. These toxins are heat labile and may be removed by heating food to high temperatures that kill the organism and neutralize the toxin. In addition to ingestion of preformed toxin in food, the organism can produce toxin within the gastrointestinal tract. Emesis is caused by the toxin, cereulide, which is heat stable and preformed in food. Cereulide toxin genes are found only in certain strains of *B. cereus*, whereas enterotoxin genes are found more broadly. Some highly pathogenic strains of *B. cereus*, which possess *B. anthracis* virulence plasmids that express anthrax toxins and have a capsule, have been isolated from animals in sub-Saharan Africa and from human cases. These strains produce a large amount of sphingomyelinase, which contributes to the pathogenicity.

CLINICAL MANIFESTATIONS

Bacillus anthracis

Anthrax manifests as four types of infection: cutaneous, inhalational, gastrointestinal, and injectional.[5] Most common is the cutaneous form, which accounts for approximately 95% of cases. Two to five days after inoculation of spores into the skin, a pruritic lesion appears as a painless papule that evolves into a vesicular stage and then to a painless black eschar surrounded by edema and a ring of vesicles, described as a "pearly wreath" (Fig. 272-2). Injectional anthrax is an unusual form of cutaneous anthrax that has been reported in injection drug users who injected heroin contaminated with *B. anthracis* into the skin or the blood stream. Skin lesions are not typical for cutaneous anthrax. Edema is prominent at the injection site.

For inhalational anthrax, the incubation period is usually 1 to 7 days but can be up to 60 days. The initial clinical presentation is nonspecific and consistent with an influenza-like illness with fever, malaise, dry cough, dyspnea, and chest pain. The hallmarks of inhalational anthrax are mediastinal lymphadenopathy, hemorrhagic mediastinitis, and pleural effusions. A chest radiograph or computed tomography (CT) scan reveals a widened mediastinum, as well as large, serosanguinous or hemorrhagic, usually bilateral pleural effusions (Fig. 272-3). High levels of lethal factor toxin have been found in pleural fluid. If treatment is delayed, patients develop severe respiratory distress and septic shock.

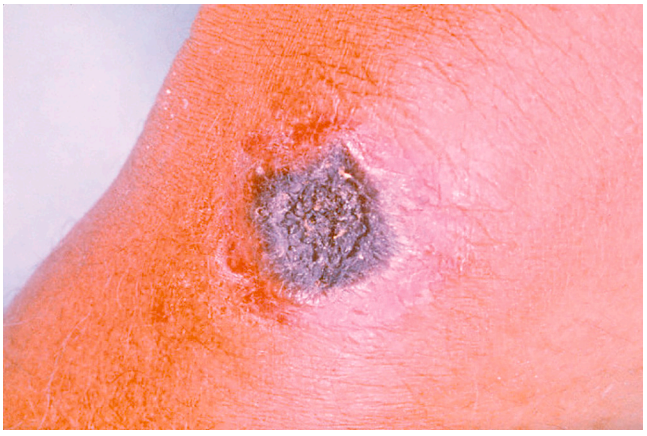

FIGURE 272-2. Cutaneous anthrax with classic black eschar. (Source: phil.cdc.gov.)

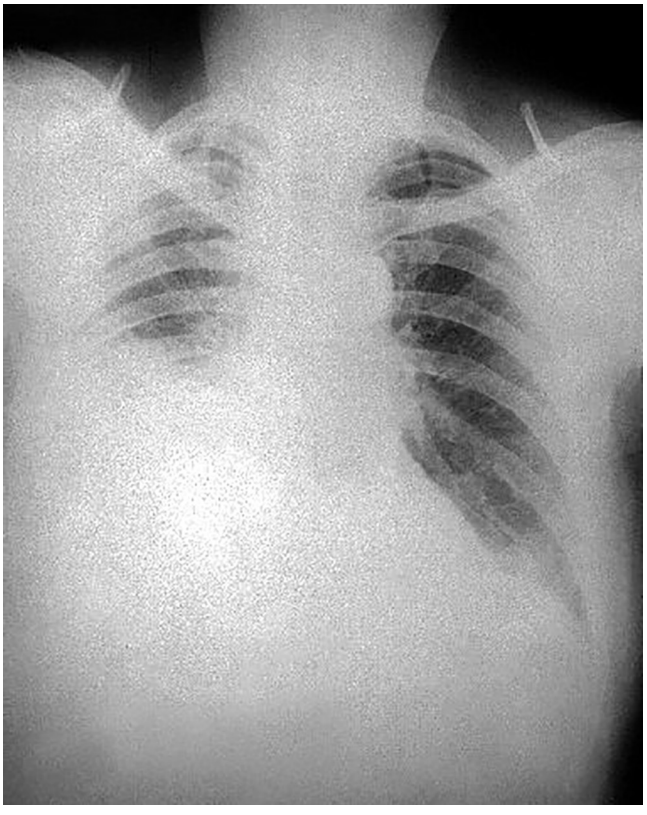

FIGURE 272-3. Chest radiograph of inhalational anthrax showing widened mediastinum and pleural effusion. (Source: phil.cdc.gov.)

Gastrointestinal anthrax, which is very uncommon and is responsible for only 1% of cases, may manifest as oropharyngeal or intestinal disease. Symptoms usually occur 1 to 5 days after ingestion of contaminated meat or drinking water. Symptoms of oropharyngeal anthrax include severe pharyngitis, dysphagia, odynophagia, and fever. Edema and lymphadenopathy may be so severe that they may cause respiratory distress. An ulcerative lesion may be seen in the mouth or pharyngeal area. Pseudomembranes may form over the lesion and may mimic diphtheria. Intestinal anthrax presents with nausea, vomiting, and fever followed by abdominal pain that may be so severe that it mimics an acute abdomen. Patients may have hematemesis, bloody diarrhea, and ascites. Secondary meningitis may occur. Gastrointestinal anthrax is likely to be associated with bacteremia/sepsis and seeding of other organs.

Anthrax meningitis occurs when bacteremia seeds the meninges during cases of inhalational or gastrointestinal anthrax. It occurs in up to 50% of inhalational cases. Symptoms and signs include severe headache, alteration of mental status, nuchal rigidity, other meningeal signs, and diffuse or focal neurologic findings. The course is frequently fulminant, with the development of delirium, seizures, and coma usually occurring within hours of initial

presentation. Cerebrospinal fluid (CSF) is hemorrhagic. Hemorrhage may also be found in the brain parenchyma and the subarachnoid space. Cerebral edema may be present.

Bacillus cereus and Other *Bacillus* Species

B. cereus causes two types of food poisoning: a diarrheal syndrome and an emetic syndrome. Similar to other toxin-mediated food poisoning (Chapter 262), the onset of symptoms with *B. cereus* occurs within 24 hours of eating the contaminated food item and usually within 8 to 16 hours. Cardinal symptoms of the diarrheal syndrome include profuse diarrhea and cramping abdominal discomfort. Fever and vomiting are rare. Onset of symptoms with the emetic form is very rapid and usually occurs within 1 to 5 hours, a time frame that is similar to food poisoning caused by *Staphylococcus aureus* (Chapter 267). Symptoms include nausea and vomiting. Diarrhea has been reported in approximately one third of cases. Both syndromes are usually self-limited and resolve within 24 hours. Rarely, the *Bacillus* toxin may lead to acute liver failure. In addition to *B. cereus*, other *Bacillus* species have been linked to food poisoning and outbreaks.

Of the systemic infections caused by *Bacillus* species, bacteremia is the most common presentation, and *B. cereus* is the most common species isolated. *B. cereus* may also cause a variety of local and systemic infections such as endocarditis; pneumonia; central nervous system (CNS) infection[6]; and infections of the urinary tract, skin, soft tissue, muscle, and wounds. Many of these infections are health care–associated (Chapter 261). Bacteremia can lead to dissemination to other body sites. Endocarditis may occur in prosthetic valves, and rare cases of native valve endocarditis are usually associated with bacteremia secondary to injection drug use. *B. cereus* can also cause eye infections, such as endophthalmitis and keratitis.[7] CNS infections, including meningitis and brain abscess, tend to occur in immunocompromised hosts, especially when they are neutropenic. When the bone marrow recovers and neutropenia resolves, immune reconstitution syndrome can be associated with a transient exacerbation of symptoms of meningitis and brain abscess.

DIAGNOSIS

Bacillus species grow readily in the laboratory on standard culture media and at temperatures of 25 to 37° C. Automated blood culture systems routinely yield growth of *B. anthracis*. Culture is the gold standard for diagnosis of anthrax infection, but polymerase chain reaction (PCR) testing can hasten the diagnosis.

Because of their ubiquitous nature in the environment and because spores can germinate rapidly on laboratory media, non-anthrax *Bacillus* species are frequent laboratory contaminants. Because *Bacillus* species rarely cause human disease and because they are such a common contaminant, identification to the species level is not commonly performed in most laboratories. However, *B. anthracis* should never be dismissed as a contaminant when it is isolated from a clinical specimen.[8]

Bacillus anthracis

For cutaneous anthrax, a Gram stain of vesicular fluid, a scraping from the base of the lesion, or a skin biopsy may show the organism. Gram stain of vesicular fluid reveals bacilli but very few leukocytes. The direct fluorescent antibody test and PCR testing can provide a rapid diagnosis. Cultures are frequently positive.

In inhalational cases, the direct fluorescent antibody test and PCR should be performed on body fluids and tissues. A Gram stain of pleural fluid may also reveal the organism. Blood and pleural fluid cultures are positive.

For suspected gastrointestinal anthrax, PCR testing as well as blood and stool cultures should be obtained. A swab of the base of an oropharyngeal lesion may reveal gram-positive bacilli; culture is frequently positive. If ascites is present, fluid should be cultured and sent for PCR testing.

Bacillus cereus and Other *Bacillus* Species

Both the diarrheal and emetic form of *B. cereus* food poisoning can be diagnosed by culturing the organism from food, stool, or vomitus. *Bacillus* species are easily cultured, but testing is not routinely performed when stool cultures are requested. PCR testing is also useful. Commercial assays for toxin testing are not widely available.

Differentiating *Bacillus* infection from contamination may be difficult. Repeated isolation from a normally sterile body fluid or site indicates infection. Most cases of true bacteremia occur in the presence of an intravascular catheter.

Serology plays a role in diagnosis and may be particularly useful when cultures and PCR are negative. Anti-protective antigen antibody is detectable approximately 1 week after the start of symptoms. Acute and convalescent samples for anti-protective antigen antibody response should be obtained in the first 7 days of illness and repeated at 14 to 28 days.

TREATMENT

Bacillus anthracis

B. anthracis is susceptible to a broad range of antibiotics, including penicillins, first-generation cephalosporins, fluoroquinolones, carbapenems, tetracyclines, macrolides, aminoglycosides, clindamycin, linezolid, rifampin, daptomycin, and dalfopristin-quinupristin.[9] For bioterrorism-associated anthrax, strains are likely to be resistant β-lactams.

The timely administration of antibiotics is essential for all forms of anthrax. For naturally occurring cutaneous anthrax with no evidence of systemic symptoms, the current treatment of choice depending on antibiotic susceptibility testing is a fluoroquinolone (e.g., ciprofloxacin 500 mg orally twice daily) or doxycycline (100 mg orally twice a day) as monotherapy for 7 to 10 days. Alternatives for adults include levofloxacin (750 mg orally once daily), moxifloxacin (400 mg orally once daily), or clindamycin (600 mg orally three times a day).[10] Penicillin VK (500 mg orally every 6 hours) or amoxicillin (1 gram orally every 8 hours) may be used once susceptibility is confirmed. For bioterrorism-related infection, the duration of therapy should be 60 days because of the risk of inhalation exposure.

All other forms of anthrax (inhalational, gastrointestinal, meningeal, injectional, and cutaneous with systemic symptoms) should be treated with two bactericidal antibiotics, a fluoroquinolone (e.g., ciprofloxacin 400 mg IV every 8 hours) plus a carbapenem (e.g., meropenem 2 g IV every 8 hours) if meningitis is suspected. If meningitis has been excluded, monotherapy with a fluoroquinolone or carbapenem should be used at the doses above. Ciprofloxacin is the preferred fluoroquinolone. For very severe or serious disease, an additional antibiotic such as linezolid (600 mg IV every 12 hours) or clindamycin (900 mg IV every 8 hours) is recommended to block protein synthesis and therefore toxin production; linezolid is preferred because of its improved CNS penetration. Penicillin G (4 million units IV every 4 hours) can be substituted for meropenem against penicillin-susceptible strains. Systemic anthrax infection should be treated with combination intravenous antibiotics for a minimum of 10 to 14 days or until clinical improvement, whichever is longer, followed by oral therapy for up to 60 days because of the long duration of viability of spores. Antitoxin therapies, such as anthrax immune globulin or one of the anti-protective antigen monoclonal antibodies (e.g., obiltoxaximab 16 mg/kg IV or raxibacumab 40 mg/kg IV [adult dosage] to 80 mg/kg IV [pediatric dose if weight is 15 kg or less])[11] may be administered along with antibiotics in severe infections, such as inhalational or systemic anthrax with signs of sepsis and in cases of serious inhalational exposures.

Serious forms of anthrax require intensive care unit management. Pleural effusions frequently require drainage. Surgical débridement may be necessary in cutaneous cases of injectional anthrax.

In the absence of controlled studies, corticosteroids (e.g., dexamethasone 10 mg intravenously then 4 mg every 6 hours until clinical improvement) may have a role in the treatment of cerebral edema and increased intracranial pressure in anthrax meningitis. Corticosteroids also have been advocated when severe edema causes airway obstruction, large pleural effusions, or massive ascites.

Bacillus cereus and Other *Bacillus* Species

Antimicrobial therapy is not indicated for the food poisoning syndromes caused by *Bacillus* species. For serious infections, the current treatments of choice are vancomycin, clindamycin, or fluoroquinolones, in consultation with an infectious disease specialist, with doses, routes, and durations varying with the type and extent of the specific infection. Dual therapy with one of these agents plus an aminoglycoside (e.g., gentamicin) may be beneficial. When *Bacillus* species bacteremia is associated with an intravascular catheter or an implanted device, removal is often necessary to effect a cure. Similarly, valve replacement is usually indicated for prosthetic valve endocarditis. Eye disease must be managed by an ophthalmologist. Keratitis can be treated with a topical fluoroquinolone, but intravitreal antibiotics and vitrectomy are indicated for endophthalmitis.

PREVENTION

Bacillus anthracis

Anthrax vaccination is recommended for adults ages 18 to 65 years who may be at risk of coming into contact with anthrax because of occupation, including U.S. military personnel, laboratory personnel who work with *B. anthracis*, and workers such as veterinarians who handle animals or animal products.[12] Vaccination is also recommended for individuals who have been exposed to anthrax in situations such as a bioterrorism attack. Anthrax vaccine adsorbed (BioThrax, licensed in the United States) may be administered as five doses intramuscularly over 18 months or as three doses over 6 months followed by an annual booster for those who continue to be at increased risk of exposure.

Anthrax vaccine precipitated (licensed in the United Kingdom) is an alternative, administered as four doses over 32 weeks followed by annual boosters. A live spore vaccine is available for veterinary use. Immunity is short-lived, so revaccination is recommended on an annual basis.

Exposed persons should receive antibiotic prophylaxis with ciprofloxacin (500 mg orally twice daily) or doxycycline (100 mg orally twice daily) for 60 days, as well as anthrax vaccine at 0, 2, and 4 weeks. Anthrax vaccine is 90% effective in protecting most people from anthrax, including the most deadly form, inhalational anthrax. Vaccination is generally well tolerated. Mild local site reactions, including myalgia at the injection site, headache, and fatigue, are the most common side effects. Persons acutely exposed to anthrax, such as during an intentional release of *B. anthracis* spores, should be decontaminated using soap and water in addition to receiving antibiotic prophylaxis.

Bacillus cereus

Prevention of *B. cereus* food poisoning is best accomplished by the safe preparation and handling of food items. Cooking food adequately kills vegetative organisms and destroys preformed diarrheal toxin but not emetic toxin. If food is not eaten in a timely fashion, it should be refrigerated as soon as possible since cold inhibits the metabolism and production of toxins.

PROGNOSIS

Mortality is approximately 20% for untreated cutaneous anthrax and approximately 30% for untreated inhalational anthrax. Skin lesions heal over a period of 1 to 3 weeks; antibiotic therapy does not affect the evolution of the localized lesion but does prevent bacteremia and serious sequelae. If untreated, inhalational anthrax has a mortality rate of 100%. With earlier recognition and timely initiation of antibiotic therapy, the case fatality rate in the 2001 bioterrorism event was 45%. Without treatment, mortality for gastrointestinal anthrax is approximately 40%. Mortality is higher (95%) if meningoencephalitis develops as a complication.

For *Bacillus* species infections, the risk of poor outcomes usually reflects the patient's underlying illness and the severity of the infection. Mortality for sepsis, meningitis, and endocarditis is higher than for catheter-related bacteremia. Endophthalmitis may lead to blindness.

DIPHTHERIA AND OTHER INFECTIONS CAUSED BY *CORYNEBACTERIA*

DEFINITION

The genus *Corynebacterium* encompasses a large group of bacteria that are typically characterized as irregularly shaped, non-spore-forming, aerobic, gram-positive rods. *Corynebacterium diphtheriae* is the causative organism for diphtheria, which is an acute illness that is mediated by toxin production and presents with a thick, adherent pseudomembrane at the site of infection. *C. diphtheriae* primarily infects the mucosa of the upper respiratory tract (e.g. nose, tonsils, pharynx, larynx), but it can also cause cutaneous disease. *Corynebacterium* species other than *C. diphtheriae* are ubiquitous in the environment (soil and water) and are commensals on skin and mucous membranes in humans. They frequently cause infection in immunocompromised hosts and in patients with indwelling devices.

The Pathogen

Corynebacteria are a heterogeneous group of pleomorphic bacteria. *Corynebacteria* are irregularly shaped, aerobic, gram-positive rods that are unencapsulated, nonmotile, not spore forming, and not acid fast. They typically form arrangements such as palisading or picket-fence configurations.

C. diphtheriae exists in toxigenic and nontoxigenic forms, with four biotypes: *gravis, mitis, intermedius, and belfanti*. Toxigenic strains carry the exotoxin (*tox*) gene that is encoded by a bacteriophage; nontoxigenic strains can be converted to toxigenic strains when the bacteriophage-encoding *tox* gene is transferred via a lysogenic cycle. *C. ulcerans* and *C. pseudotuberculosis*, which are members of the *C. diphtheriae* group, are able to produce diphtheria-like toxin, with similar clinical presentations as *C. diphtheriae*.

EPIDEMIOLOGY

C. diphtheriae

Humans serve predominantly as the natural host for *C. diphtheriae*, but the organism has been isolated from other animal hosts (including domestic animals) on rare occasions. Transmission of infection occurs with close contact, either through inhalation of infected respiratory droplets or through direct contact with infected respiratory secretions or cutaneous lesions. *C. diphtheriae* can survive in the environment for several weeks, and transmission via fomites also occurs. Asymptomatic carriers of *C. diphtheriae* serve as the reservoir for sustained transmission.

In the prevaccine era, diphtheria was a major contributor to morbidity and mortality globally. Nearly 70% of cases occurred in children under the age of 15, with case fatality rates of 5 to 10%. With the widespread use of the diphtheria toxoid vaccine, the annual number of cases of respiratory diphtheria worldwide has steadily declined since the 1980s from approximately 100,000 cases in 1980 to fewer than 9000 in 2017, and most cases in developed countries are attributable to nontoxigenic strains of *C. diphtheriae*.[13] In the United States, only 14 cases of respiratory diphtheria were reported between 1996 and 2018, and only one of the five cases that was culture positive for *C. diphtheriae* was toxigenic.[14]

Nevertheless, large outbreaks of diphtheria have occurred even in the vaccine era, typically in the setting of social or political upheaval. The largest recent resurgence occurred from 1990 to 1998 in several countries of the former Soviet Union, where over 157,000 cases and 5000 deaths were reported. More recent outbreaks have occurred in South America, including Brazil and Venezuela; Southeast Asia, including Indonesia, Thailand, and Laos; Yemen; and Haiti. In developing countries, diphtheria remains a serious disease, especially in areas where access to routine vaccinations is suboptimal. Diphtheria remains endemic in India.

Vaccine-induced immunity wanes over time; older adults who do not receive a booster dose of diphtheria toxoid vaccine are at risk for acquiring infection. A seroprevalence survey in the United States demonstrated diminished levels of protective diphtheria antitoxin antibodies for adults age 70 years and older.

Other *Corynebacteria*

To date, over 100 *Corynebacteria* species other than *C. diphtheriae* have been identified. Although recovery of *Corynebacteria* from clinical specimens was traditionally considered to represent contamination, increasing evidence indicates that *Corynebacteria* cause significant clinical disease, especially in hospitalized and immunocompromised patients.

PATHOBIOLOGY

C. diphtheriae

Respiratory diphtheria occurs when *C. diphtheriae* infects the mucosal surface of the upper airway tract, including the nasopharynx, larynx, or, less commonly, trachea or bronchus. Clinical signs and symptoms are due to exotoxin produced by replicating bacteria. Diphtheria exotoxin is a potent inhibitor of elongation factor 2, which is essential for protein synthesis. Toxin-mediated effects lead to local tissue edema, necrosis, and ulceration. The hallmark of toxin-mediated disease is the development of an adherent pseudomembrane that is composed of fibrin, nonviable epithelial cells, inflammatory cells, and organisms. Typically, pseudomembranes begin in the tonsils, the pharynx, or the nares. In severe cases, pseudomembranes can extend to the larynx or trachea and lead to airway obstruction. Toxin can disseminate hematogenously and cause disease in other organs, including the myocardium, nerves, and kidneys. Nontoxigenic strains rarely produce pseudomembranes, and respiratory disease tends to be milder.

Other *Corynebacteria*

C. ulcerans and *C. pseudotuberculosis* are primarily animal pathogens, but zoonotic disease has been reported in humans. Both *C. ulcerans* and *C. pseudotuberculosis* may produce diphtheria-like toxin and can cause toxin-meditated disease. Other *Corynebacteria* typically cause organ-specific disease that is not toxin-mediated.

CLINICAL MANIFESTATIONS

C. diphtheriae

Respiratory Diphtheria

The most common form of respiratory disease involves the pharyngeal area. After an incubation period of 2 to 5 days (range: 1 to 10 days), prodromal signs and symptoms include sore throat, cervical lymphadenopathy, malaise, and low-grade fever. Approximately 80% of untreated symptomatic cases develop membranous diphtheria two to three days after the onset of prodromal symptoms.[15] Pharyngeal erythema is followed by a whitish exudate that becomes a grayish pseudomembrane in the ensuing 1 to 2 days; the pseudomembrane is firmly adherent to the underlying mucosa and bleeds upon forceful removal.

The bull neck appearance associated with diphtheria is attributable to cervical lymphadenopathy and localized soft tissue edema. Complications from pharyngeal disease include stridor, airway obstruction, and respiratory compromise. Pseudomembranes can extend from the pharyngeal area to the nasal passages and the tracheobronchial tree.

Other areas of involvement in respiratory diphtheria include the anterior nares, laryngeal, and tracheobronchial areas. Nasal diphtheria, which typically tends to be mild, presents with serosanguinous or purulent discharge. Laryngeal diphtheria presents with hoarseness, stridor, and cough. Tracheobronchial infection is usually due to secondary spread of pseudomembranes and can lead to respiratory compromise. Severe clinical disease increases the risk of the absorption and dissemination of toxin.

Cardiac and Neurologic Toxicity

Toxin-mediated cardiac disease occurs in up to 25% of respiratory diphtheria cases. The risk of cardiac complications increases if antitoxin therapy is delayed or not administered. Myocarditis (Chapter 47), which is the most common manifestation of cardiac toxicity, typically develops during the first or second week of infection. Clinical symptoms consistent with myocarditis are nonspecific but include heart failure and diminished cardiac output. Abnormalities on electrocardiography include ST-T wave changes, heart block, and arrhythmias. In one study of 99 children in India with diphtheria, 35% developed myocarditis and 11% developed cardiogenic shock.[16]

Neurologic disease due to toxin-producing *C. diphtheriae* is less common than cardiac disease. During the acute phase, local motor neuropathy manifests with paralysis of the soft palate and pharynx. Cranial neuropathies can cause further paralysis of the larynx, facial oculomotor, and ciliary muscles. Peripheral neuritis with predominant motor deficits typically occurs 2 weeks to 3 months after the resolution of respiratory symptoms.

Cutaneous Diphtheria

Asymptomatic skin carriage serves as a reservoir for infection. Symptomatic cutaneous diphtheria,[17] which is usually caused by nontoxigenic strains, typically presents as chronic, nonhealing, deep ulcers that may have a grayish-white pseudomembrane. Infection may occur in preexisting chronic dermatoses or manifest as impetigo (Chapter 408). Co-infection with *Staphylococcus aureus* and *Streptococcus pyogenes* can occur.

Other *Corynebacteria*

Infections due to other *Corynebacteria* are broadly categorized as community acquired or health care–associated (Tables 272-2 and 272-3), but zoonotic infections also occur. Community-acquired infections include pharyngitis, skin and soft tissue infections, genitourinary tract infections, and ocular infections. Health care–associated infections include device-related infections, native and prosthetic valve endocarditis, postsurgical infections, and genitourinary tract infections.

Nonlipophilic, Fermentative *Corynebacteria*

Corynebacterium ulcerans and *C. pseudotuberculosis*, which are members of the *C. diphtheriae* group, are primarily animal pathogens. In humans, *C. ulcerans* causes exudative pharyngitis and cutaneous disease that is similar to *C. diphtheriae*[18]; it also can produce diphtheria toxin–mediated disease and complications. *C. pseudotuberculosis* infection in humans typically manifests as granulomatous lymphadenitis that mainly affects individuals who work with infected animals.

Several *Corynebacterium* species (including *C. xerosis*, *C. striatum*, *C. amycolatum*, and *C. minutissimum*) are normal skin commensals. Infections due to these organisms predominantly occur in the skin and soft tissue, often as health care–associated infections (Table 272-3).[19] *C. glucuronolyticum* and *C. riegelii* are associated with genitourinary tract infections in males and females, respectively.

Nonlipophilic, Nonfermentative *Corynebacteria*

Corynebacterium pseudodiphtheriticum is a normal commensal of the upper respiratory tract. Co-circulation with *C. diphtheriae* has been described. Infections primarily occur in immunocompromised hosts and in patients with chronic lung disease. In addition to causing respiratory disease, *C. pseudodiphtheriticum* has been implicated in infections of heart valves and the cornea. Similarly, *C. propinquum* has been associated with respiratory infections, endocarditis, and keratitis.

Lipophilic *Corynebacteria*

Corynebacterium jeikeium has been associated with severe disease in hospitalized patients, especially in immunocompromised hosts, patients with indwelling devices, and patients with prolonged hospitalization (Chapter 261) or exposure to multiple broad-spectrum antibiotics.[20] Infection due to *C. jeikeium* typically presents as septicemia due to infected indwelling devices, native and prosthetic

valve endocarditis, prosthetic joint infection, and CNS infection. *C. urealyticum* causes chronic and recurrent urinary tract infection, including encrusted cystitis and pyelitis, especially in patients who have abnormal urinary tract anatomy or indwelling urinary catheters, or who have had urinary tract procedures; it has also been implicated in sepsis, endocarditis, and osteomyelitis. Other notable lipophilic *Corynebacteria* include *C. macginleyi* (keratitis) as well as *C. kroppenstedtii* and *C. tuberculostearicum* (mastitis and breast abscess).

DIAGNOSIS

C. diphtheriae

Prompt diagnosis and treatment is paramount in preventing severe outcomes. Infection due to *C. diphtheriae* should be considered when a patient presents with consistent clinical signs and epidemiologic risk factors, including residence in or travel from an endemic area or a history of inadequate vaccination. Other infections in the differential diagnosis include streptococcal pharyngitis (Chapter 269), infectious mononucleosis (Chapter 348), Vincent angina (Chapter 397), acute epiglottitis (Chapter 397), oropharyngeal candidiasis (Chapter 310), and acute retroviral syndrome due to human immunodeficiency virus (HIV) infection (Chapter 355).

Clinical samples should be collected via swabbing the affected areas, including the nasopharynx, throat, and suspicious skin lesions. If a pseudomembrane is present, a sample should be obtained from underneath the membrane, or a piece of the membrane can be submitted. The microbiology laboratory should be notified about the specific concern for *C. diphtheriae*, because special media is required. Mass spectrometry[21] and PCR testing are highly accurate in identifying *Corynebacterium* species, including *C. diphtheriae*. All *C. diphtheriae* isolates should be tested for toxin production. Cultures should be obtained regardless of whether treatment has been initiated.

Other *Corynebacteria*

Because *Corynebacteria* are often cultured in polymicrobial infections or as a contaminant due to nonsterile collection technique, the microbiology laboratory should be informed when species identification is appropriate. PCR and mass spectrometry can identify *Corynebacteria* to the species level.

TREATMENT

C. diphtheriae

The mainstay of treatment for respiratory diphtheria includes administration of diphtheria antitoxin and antibiotic therapy. Treatment should be initiated promptly in cases of suspected disease to optimize favorable outcomes and mitigate potential complications. Supportive care and prevention of further transmission are additional treatment goals (Table 272-4).

Administration of diphtheria antitoxin within the first 48 hours of symptoms provides the greatest benefit in terms of halting disease progression. Diphtheria antitoxin is administered as a single dose, ranging from 20,000 units for localized tonsillar disease of 2 days duration or less, to 100,000 units for extensive disease of 3 days duration or more or for severe toxicity. Children and adults receive the same dose; routes of administration include intramuscular and intravenous, with the latter being preferred for severe cases. In the United States, diphtheria antitoxin can be obtained from the Centers for Disease Control and Prevention (CDC) under the Investigational New Drug protocol (770-488-7100; www.cdc.gov/diphtheria/downloads/protocol.pdf). To mitigate hypersensitivity reactions or serum sickness, allergy testing should be performed, followed by desensitization if necessary.

Effective antibiotic therapies to eliminate the organism and thereby its production of toxin require 14 days of treatment, usually with erythromycin (orally or intravenously at 40 to 50 mg/kg/day, up to 2 g daily in four divided doses) or intramuscular procaine penicillin G (25,000 to 50,000 units/[kg/day] for children and 1.2 million units/day for adults, in two divided doses), with transition to oral penicillin V (125 to 250 mg four times daily) when the patient is able to tolerate oral intake.[22]

Supportive care includes close monitoring of respiratory, cardiac, and neurologic status. Preemptive intubation may be needed in cases of potential respiratory failure due to airway obstruction from membranous disease. Continuous cardiac monitoring is necessary to detect and treat cases of myocarditis (Chapter 47), heart failure (Chapter 46), and arrhythmias (Chapter 49) promptly. During convalescence, diphtheria toxoid vaccine should be administered, because natural immunity may not confer protection against toxin.

For respiratory diphtheria, respiratory droplet precautions should be maintained until the patient has received 14 days of antibiotic therapy and two consecutive sputum cultures taken 24 hours apart are negative after completion of antibiotics. The local health department should be notified.

TABLE 272-4 GOALS AND INTERVENTIONS FOR SUSPECTED DIPHTHERIA

GOAL	INTERVENTION
Toxin neutralization to decrease risk of severe complications and death	Obtain and administer diphtheria antitoxin after presumptive diagnosis of diphtheria
Effective eradication of organism	Initiation of appropriate antibiotic therapy
Support acutely ill patients requiring hospitalization	Provide appropriate and intensive monitoring within the hospital setting
Confirmation of diagnosis	Collect appropriate specimens for microbiologic testing (culture, PCR, mass spectrometry)
Prevention of transmission of diphtheria	Strict respiratory isolation of index case Notification of health department Initiate postexposure prophylaxis of close contacts
Long-term protection against diphtheria in case and close contacts	Administer diphtheria toxoid vaccine as needed

PCR = polymerase chain reaction.

Other *Corynebacteria*

Isolates that are implicated in causing clinical disease should undergo susceptibility testing. *Corynebacteria* generally are susceptible to vancomycin and linezolid, with dosing and duration requiring consultation with an infectious disease expert.

PREVENTION

C. diphtheriae

Diphtheria toxoid vaccine is approximately 95% effective in adequately immunized persons and is protective for at least ten years. In the United States, diphtheria toxoid is administered as a component of diphtheria toxoid, tetanus toxoid, and acellular pertussis combination vaccines (DTaP or Tdap). A booster dose of Tdap is recommended for adolescents age 11 to 12 years, mostly to provide protection against pertussis, and then as often as every ten years in adults in the United States (see Chapter 15 and https://www.cdc.gov/vaccines/vpd/dtap-tdap-td/hcp/recommendations.html), but not by the World Health Organization because the benefit of diphtheria re-vaccination in adults is likely very small, at best.[23] Pregnant women should receive one dose of Tdap at 27 to 36 weeks of gestation.

Close contacts of cases, including household contacts, should be administered prophylactic antibiotics with either one dose of intramuscular benzathine penicillin G (600,000 units for persons <6 years of age, or 1,200,000 units for ≥6 years of age) or a 7- to 10-day course of oral erythromycin (40 mg/kg/day for children; 1 g/day for adults). Cultures should be obtained prior to and after completion of antibiotics; if cultures are positive after antibiotic therapy, an additional 10 days of treatment with erythromycin is warranted. An age-appropriate booster dose of a diphtheria toxoid–containing vaccine should be administered; all contacts who have not received a booster dose in the past 5 years should be administered diphtheria toxoid vaccine.

Other *Corynebacteria*

Prevention of infection caused by *Corynebacteria* include proper skin antisepsis prior to invasive procedures and good hand hygiene when handling animals.

PROGNOSIS

C. diphtheriae

Although diphtheria cases worldwide have diminished after introduction of the vaccine, case fatality rates remain high. For example, the case fatality rate in the Philippines is over 40%.[24] Timely administration of antibiotics and diphtheria antitoxin can reduce morbidity and mortality. Myocarditis can progress to cardiogenic shock, but neurologic disease usually resolves.

Other *Corynebacteria*

Overall outcomes for infections attributable to *Corynebacteria* are favorable, based on proper identification, antimicrobial therapy, and removal of indwelling devices, if appropriate.

ERYSIPELOID AND OTHER *ERYSIPELOTHRIX* INFECTIONS

DEFINITION

Erysipelothrix rhusiopathiae, which is a zoonotic pathogen, causes three well-defined patterns of human infection: erysipeloid, which is a cellulitis of the fingers and hands (also known as whale finger or pork finger) and is the most common manifestation of infection with *E. rhusiopathiae*; a diffuse cutaneous form; and a systemic or invasive form, with or without cutaneous involvement, usually manifesting as bacteremia that may be complicated by endocarditis.

The Pathogen

E. rhusiopathiae is a thin, pleomorphic, nonsporulating, microaerophilic, gram-positive rod. It may be confused with other gram-positive bacillary organisms, particularly *Listeria monocytogenes* and *Corynebacterium* species. It does not produce toxin. It can be differentiated from *L. monocytogenes* by its lack of motility, lack of catalase and coagulase production, and resistance to neomycin. Most strains of *E. rhusiopathiae* produce hydrogen sulfide on triple sugar iron agar slants, a feature that distinguishes *E. rhusiopathiae* from *L. monocytogenes* and from corynebacteria. Because α-hemolysis may be seen after 48 hours of incubation of *E. rhusiopathiae*, it can be confused with streptococci. The term *erysipeloid* refers to cutaneous infection by *E. rhusiopathiae* (Fig. 272-4) and should not be confused with erysipelas, which is a superficial cellulitis caused by streptococci or staphylococci.

EPIDEMIOLOGY

E. rhusiopathiae is found worldwide as a commensal or as a pathogen in a variety of wild and domestic animals, including swine, sheep, cattle, horses, dogs, cats, rodents, chickens, ducks, turkeys, penguins, and parrots, as well as in flies, ticks, mites, and lice. The greatest commercial impact of *E. rhusiopathiae* infection is due to disease in swine, but infection of sheep and poultry is also important economically. Environmental surfaces in contact with infected animals, their bodily fluids, or their products are potential sources of *E. rhusiopathiae*. It can persist for prolonged periods in contaminated soil. *E. rhusiopathiae* is killed within 15 minutes by heating to 55° C and by several commercially available home disinfectants.

The incidence of cutaneous infection in humans seems to be decreasing because of technologic advances in animal industries. Infection is usually the result of contact with infected animals or their products. Persons at greatest risk for infection include fishers, fishmongers, farmers, butchers, slaughterhouse workers, and veterinarians. The organism gains entry through cuts and abrasions on the skin and can result in infection from freshwater or seawater.[25] The seasonal incidence of erysipeloid parallels that of swine erysipeloid and is highest in the summer and early fall. The rare instances of systemic infection without an occupational link tend to occur in immunocompromised hosts, thereby suggesting that oropharyngeal or gastrointestinal colonization with the organism may occur. Chronic alcohol use disorder (Chapter 364) is a common underlying condition. Erysipeloid and erysipeloid with bacteremia have been reported rarely after cat and dog bites, thereby suggesting that *E. rhusiopathiae* may be part of the oral flora of these animals.

FIGURE 272-4. Erysipeloid with its characteristic purple, nonpurulent swelling of the finger. Also known as whale finger or pork finger, this form of cellulitis caused by *Erysipelothrix rhusiopathiae* should not be confused with streptococcal or staphylococcal erysipelas (see Fig. 408-4). (From Farrar WE, Wood MJ, Innes JUA, Tubbs H. *Infectious Diseases: Text and Color Atlas*. 2nd ed. New York: Gower Medical Publishing; 1992.)

PATHOBIOLOGY

The pathogenesis of *E. rhusiopathiae* infection is not well understood. Strains vary in virulence. Virulence is associated, at least in part, with resistance to phagocytosis by polymorphonuclear leukocytes. This antiphagocytic ability results from the organism's possession of a capsule. In the absence of specific antibodies, *E. rhusiopathiae* evades phagocytosis, but even if it is phagocytosed, it is able to replicate intracellularly in these cells. Other virulence factors include enzymes (neuraminidase and hyaluronidase) and cell wall–associated proteins, including transporter and adhesion proteins, such as SpaA, which acts as an adhesion to host endothelial cells.[26]

CLINICAL MANIFESTATIONS

Because of the mode of acquisition (contact with infected animals or their products, with organisms inoculating abrasions on the skin), lesions are usually confined to the fingers and hands (Fig. 272-4). A well-defined, slightly elevated, violaceous lesion accompanied by a very painful, throbbing, burning, or itching sensation develops within 2 to 7 days of traumatic dermal inoculation.[27] The infected area is swollen. Vesicles may be present, but suppuration is absent. The lesion spreads slowly to other fingers but rarely involves the fingertips or the skin above the wrist. As the lesion spreads peripherally, the central area clears. Systemic signs and symptoms are rare. Sterile arthritis may involve an adjacent joint. Regional lymphadenopathy or lymphadenitis occurs in about 20% of cases, and low-grade fever develops in approximately 10%. Lesions usually resolve within 3 weeks without treatment. Relapse occurs in 1% of cases.

The diffuse cutaneous form is rare. The cutaneous lesion progresses proximally from the site of inoculation or appears at remote areas. Patients often have fever and arthralgias, but blood cultures are generally negative.

Systemic infection with *Erysipelothrix* is uncommon, but bacteremia can result in endocarditis (Chapter 61), often on an apparently normal valve.[28] The presentation can be acute or subacute. One third of patients have an antecedent or concurrent skin lesion of erysipeloid. *E. rhusiopathiae* endocarditis correlates highly with occupation, exhibits a tropism for the aortic valve, affects more males than females, and is associated with high mortality, which may reflect a delay in appropriate therapy because of the empirical use of vancomycin, which is not an effective treatment of *E. rhusiopathiae*. About one-third of patients require valve replacement. *E. rhusiopathiae* bacteremia is increasingly seen in immunocompromised patients. Focal infections include brain abscess, meningitis, endophthalmitis, osteomyelitis, septic arthritis, epidural and paravertebral abscess, psoas abscess, liver abscess, necrotizing fasciitis, intra-abdominal abscess, and peritonitis. Septic arthritis can occur in native joints, in prosthetic joints, and after arthroscopic surgery. Peritonitis can complicate peritoneal dialysis.

DIAGNOSIS

Diagnosis requires a high degree of suspicion in patients who have exposures, which are usually work-related. Because *E. rhusiopathiae* is located only in deeper parts of the skin in cases of erysipeloid, biopsy of the entire thickness of the dermis from the edge of the lesion maximizes the recovery of the organism. PCR or mass spectrometry (MALDI TOF) improves the efficiency of detection and identification compared with waiting for the culture results.[29] Definitive diagnosis by skin biopsy is rarely necessary because of the classic clinical presentation and the rapid response to therapy. Routine blood culture techniques are adequate for growth and isolation of the organism in suspected cases of bacteremia or endocarditis.

TREATMENT

Penicillin G is the treatment of choice. Although erysipeloid skin lesions may resolve spontaneously, cutaneous lesions generally respond well to a 5- to 7-day course of oral penicillin VK (250 mg four times daily). Treatment hastens healing, but relapse may still occur. Bacteremia should be treated with intravenous penicillin (2 to 4 million units every 4 hours for 2 weeks). Endocarditis can be treated with intravenous penicillin G (12 million to 20 million units daily) or ceftriaxone (1 g daily) for 4 to 6 weeks, but 2 weeks of intravenous therapy followed by 2 weeks of oral therapy has been successful. Bone and joint infections require longer courses of antibiotics (at least 12 weeks). The use of quinolones or daptomycin may be considered for *Erysipelothrix* infections when the patient is allergic to β-lactams. Valve replacement may be necessary in patients with endocarditis. Infected prosthetic devices should be removed.

PREVENTION

Proper cleaning and disinfection of work surfaces and attention to hygienic work practices, including the use of gloves and hand hygiene, reduce the risk for infection. Vaccines are available for commercial use in animals only.

LISTERIOSIS

DEFINITION

Listeriosis is a food-borne infection.[30] Most infected patients have impaired cell-mediated immunity and develop life-threatening bacteremia or meningitis. However, a self-limited, febrile gastroenteritis also occurs in healthy persons.

The Pathogen

Listeria monocytogenes is a gram-positive rod that is facultatively anaerobic and does not produce endospores. The organism exists intracellularly, and it is catalase positive and beta-hemolytic when grown on blood agar.

EPIDEMIOLOGY

Widely distributed in nature, *L. monocytogenes* may be found in soil, on vegetation, and in the stool of healthy mammals, including humans. The organism causes disease in animals, especially herd animals, and in humans. *L. monocytogenes* has been isolated from many foods, including raw produce, raw milk, milk products, cheeses, ice cream, fish, poultry, and meat. Unlike most food-borne pathogens, *L. monocytogenes* can grow at refrigerator temperatures.

Non-perinatal listeriosis is almost always the result of food-borne infection. Listeriosis is a relatively rare food-borne illness (about 1% of U.S. cases). Outbreaks have been documented in association with coleslaw, milk, soft cheeses, ice cream,[31] pâté, ready-to-eat pork products, deli counter meats, hot dogs, smoked fish, butter, sprouts, taco or nacho salads, and cantaloupes.[32]

Listeriosis is a nationally reportable disease. Centers for Disease Control and Prevention's PulseNet (http://www.cdc.gov/pulsenet/) facilitates prompt detection of disease clusters that may have a common source. Each outbreak of listeriosis has a median of four cases. In 2019, the annual incidence of listeriosis in the United States was 0.3 cases per 100,000 population, and it accounted for 134 cases per year and 21 deaths. Neonates and adults older than age 60 years, and especially over age 85 years,[33] have the highest infection rates, and pregnant women represent 14% of all affected individuals. Other adults at increased risk for invasive listeriosis (bacteremia) include patients who have hematologic malignancies, advanced acquired immunodeficiency syndrome (AIDS), or a solid organ transplant, as well as any patients who are being treated with corticosteroids or an anti–tumor necrosis factor agent. Iron is a virulence factor for *L. monocytogenes*, and patients who have iron overload states (Chapter 196) are at increased risk for *Listeria* infection. Use of proton pump inhibitors also increases the risk of infection. However, as many as 25% of all cases of invasive listeriosis occur in apparently healthy persons, particularly individuals older than age 60 years.

PATHOBIOLOGY

L. monocytogenes enters the human body through the intestine, most often after the ingestion of contaminated food. The bacterium induces its own uptake by gastrointestinal cells and macrophages. Infectious or mechanical disruption of the gastrointestinal tract occasionally may promote invasion. Mother-to-child transmission occurs transplacentally or through a colonized birth canal. Within the host cell, the bacterium is enclosed in a phagolysosome, but it produces an exotoxin called listeriolysin O that destroys the phagolysosome membrane and gains access to the cytoplasm. All pathogenic strains of *L. monocytogenes* produce listeriolysin O, the major virulence factor. Phosphocholine antagonizes listeriolysin O–induced host cell responses through enzymatic activity. Listeriae actively divide in the cytoplasm, migrate to the periphery of the cell by polymerization of host cell actin, and then push out the cell membrane to form pseudopods, which are taken up by adjacent host cells. The bacteria move from cell to cell in this fashion and repeat their life cycle without exposure to antibodies or complement.

After translocation through the gastrointestinal tract, listeriae may disseminate hematogenously to any body site, but show a particular tropism for the CNS. Less commonly, they may spread intra-axonally through cranial nerves to reach the CNS; this mode of CNS invasion may result in rhombencephalitis (brain stem infection).

Immunity to infection with *Listeria* is handled chiefly through the cell-mediated arm of the immune system. Persons who have had a splenectomy or who have abnormalities solely of humoral immunity or leukocytes are not at increased risk for infection.

CLINICAL MANIFESTATIONS

Food-borne outbreaks after ingestion of *L. monocytogenes* in a sufficiently large inoculum can result in a self-limited illness consisting of fever, chills, diarrhea, abdominal cramps, and sometimes nausea and vomiting. Symptoms follow exposure by 1 to 2 days and persist for about 2 days.

The incubation period for invasive listeriosis averages about 11 days, and 90% of infections occur within 28 days. Listeriosis in an immunocompromised adult or pregnant woman is most often manifested as bacteremia without an obvious focus. In these cases, patients have nonspecific symptoms, such as fever, malaise, myalgia, and back pain. Listeriosis during pregnancy may lead to spontaneous abortion or neonatal sepsis, but early antimicrobial therapy may result in the birth of a healthy child (fetal viability 29% in second trimester; 95% in third trimester). Endocarditis with *L. monocytogenes* can occur on both native and prosthetic valves, and it carries a high rate of septic complications.[34]

L. monocytogenes bacteremia may progress to CNS infection, most commonly manifested as meningitis,[35] and *L. monocytogenes* is the most common cause of bacterial meningitis (Chapter 381) in patients with lymphomas, in organ transplant recipients, and in patients treated with corticosteroids for any reason. Affected persons may have the classic acute symptoms of meningitis, but the presentation is subacute (>24 hours) in many cases. Nuchal rigidity is present in 80%. Focal neurologic findings, including ataxia, tremors, myoclonus, and seizures, may be seen, consistent with the tropism of *Listeria* for brain parenchyma.

Meningitis can be accompanied by brain abscesses, which are often subcortical. *L. monocytogenes* is also a rare cause of encephalitis.

Listerial rhombencephalitis is an unusual form of listerial encephalitis that involves the brain stem and, unlike other listerial CNS infections, usually occurs in healthy adults.[36] The typical clinical picture is a biphasic illness with a prodrome of fever, headache, nausea, and vomiting that persists for about 4 days and is followed by the abrupt onset of asymmetrical cranial nerve deficits, cerebellar signs, and hemiparesis or hemisensory deficits or both. Respiratory failure develops in about 40% of patients. Nuchal rigidity is present in about half, and CSF findings are only mildly abnormal, with a positive CSF culture in about 40%. Almost two thirds of patients are bacteremic.

Localized infection may occur after hematogenous seeding (e.g., liver abscess, septic arthritis) or, rarely, after direct inoculation (e.g., papulopustular rash or conjunctivitis). Osteoarticular listeriosis primarily involves prosthetic joints, especially in immunocompromised patients. *L. monocytogenes*–associated pneumonia and empyema have also been reported.

DIAGNOSIS

Differential Diagnosis

Clinical situations in which a diagnosis of listeriosis should be considered include:

- Neonatal sepsis or meningitis
- Meningitis or parenchymal brain infection in patients with subacute presentations, hematologic malignancies, AIDS, organ transplantation, corticosteroid immunosuppression, treatment with anti–tumor necrosis factor agents, or age older than 50 years
- Simultaneous infection of the meninges and brain parenchyma
- Subcortical brain abscess
- Fever during pregnancy
- Blood, CSF, or other normally sterile specimen reported to have "diphtheroids" on Gram stain or culture
- Food-borne outbreak of febrile gastroenteritis when routine cultures fail to identify a pathogen

The differential diagnosis of listerial CNS infection includes the more common causes of bacterial meningitis (Chapter 381) and brain abscess (Chapter 382). Listerial meningitis or rhombencephalitis may mimic CNS tuberculosis (Chapter 299).

Laboratory

The diagnosis of listeriosis is made by routine bacterial culture of specimens from usually sterile sites, such as blood or CSF. Gram stain of CSF reveals small gram-positive rods in only about one third of cases. The glucose content in CSF is normal in more than 60% of cases; mononuclear cells predominate in 30%. *L. monocytogenes* can rarely cause recurrent meningitis. Real-time PCR analysis of CSF for the *hly* gene, which encodes listeriolysin O, has been useful in diagnosing CNS listeriosis, including cases in which

routine bacterial cultures were negative,[37] but this test is not commercially available. Magnetic resonance imaging is superior to CT for demonstrating rhombencephalitis.

Specific stool culture is recommended only when routine stool cultures are negative in the setting of an outbreak of gastroenteritis; many people have enteric colonization with *L. monocytogenes* without invasive disease. The laboratory must be advised that listerial infection is suspected because the organism is unlikely to be identified with routine stool culture media. Whole-genome sequencing enhances the real-time detection and investigation of listeriosis outbreaks. Serologic testing (antibody to listeriolysin O) is not useful for invasive disease but may be helpful in the retrospective identification of food-borne outbreaks of febrile gastroenteritis when routine cultures are negative.

Endocarditis, but not bacteremia per se, may be a clue to underlying colon cancer. Colonoscopy should be considered in all cases of listerial endocarditis.

TREATMENT

Because 20% of cases of bacterial meningitis in patients older than age 50 years are due to *L. monocytogenes*, empirical therapy for bacterial meningitis (Chapter 381) in all adults older than age 50 years should include either ampicillin or trimethoprim-sulfamethoxazole, especially in the absence of associated pneumonia, otitis, sinusitis, or endocarditis, which would suggest a cause other than *L. monocytogenes*. Cephalosporins, commonly used for the treatment of bacterial meningitis, should not be used alone when *Listeria* is a diagnostic consideration.

For confirmed cases of listeriosis, ampicillin (2 grams IV every 4 hours) is generally the drug of choice. In cases of meningitis and endocarditis and in patients with severely impaired T-cell function, gentamicin (2 mg/kg IV load and then 1.7 mg/kg every 8 hours, adjusting dose and frequency for renal function and monitoring blood levels to avoid toxicity) is usually added to ampicillin. For meningitis, therapy should be continued for at least 3 weeks; bacteremic patients without CNS involvement may be treated for 2 weeks. Endocarditis and brain abscess should be treated for at least 6 weeks. Meningitis doses should be used to treat all cases of invasive listeriosis, even in the absence of CNS or CSF abnormalities. In patients with penicillin hypersensitivity, trimethoprim-sulfamethoxazole (5 mg/kg trimethoprim component IV every 6 to 8 hours) is the preferred agent and appears to be as effective as the combination of ampicillin and gentamicin. The role of corticosteroids in the treatment of listerial CNS infection is unknown.

Infection of a prosthetic joint usually can be cured only by removing the infected implant. In patients with listeriosis and iron deficiency, it may be prudent to withhold iron replacement until antimicrobial therapy is complete.

PREVENTION

Guidelines for preventing listeriosis are similar to those for preventing other food-borne illnesses: thoroughly cooking raw food from animal sources; washing raw vegetables thoroughly before eating; keeping uncooked meats separate from vegetables and from cooked and ready-to-eat foods; avoiding raw (unpasteurized) milk or foods made from raw milk; and washing hands, knives, and cutting boards after each handling of uncooked foods.

Immunocompromised patients, pregnant women, and the elderly may choose to avoid soft cheeses such as feta, Brie, Camembert, blue-veined, and Mexican-style cheese such as queso fresco. Leftover foods or ready-to-eat foods, such as hot dogs, should be cooked until steaming hot. It is best to avoid foods from delicatessen counters, such as prepared salads, meats, and cheeses.

Listeriosis is effectively prevented by trimethoprim-sulfamethoxazole given as *Pneumocystis* prophylaxis (Chapter 313) to organ transplant recipients, patients who are receiving corticosteroid immunosuppression, or HIV-infected individuals. Except for transmission from infected mother to fetus, human-to-human transmission of listeriosis does not occur, so patients do not need to be isolated.

PROGNOSIS

Listeria meningitis carries an overall mortality rate of about 25%. Listeriosis causes approximately 20 to 30% of all food-borne disease–related deaths. The mortality rate is higher in patients with underlying malignant disease. Mortality from endocarditis and brain abscess is about 50%, and survivors of brain abscess or rhombencephalitis commonly have significant neurologic sequelae.

273 DISEASES CAUSED BY NON–SPORE-FORMING ANAEROBIC BACTERIA

ITZHAK BROOK

DEFINITION

Anaerobic bacteria are the predominant members of the indigenous microbiota, including the skin and the oral, gastrointestinal, and vaginal mucosa (Fig. 273-1; Table 273-1). However, the types of predominant anaerobes differ by location.

The Pathogens

Advances in taxonomics have led to reclassification of many anaerobic species (E-Table 273-1) over the past several decades. *Fusobacterium nucleatum* is the predominant *Fusobacterium* species isolated from clinical specimens.

EPIDEMIOLOGY

Anaerobes are opportunistic pathogens that can cause serious infections, generally synergistic infections in combination with aerobic bacteria. Because the microbiology of these infections is often complex and because culture results may be delayed, awareness of the normal bacterial microbiota at the site of infection is an indispensable guide for the selection and institution of empirical antimicrobial therapy.

PATHOBIOLOGY

Anaerobic bacteria range from those that cannot survive even a brief exposure to oxygen to those that can survive even in the presence of atmospheric oxygen (e.g., *B. fragilis*). Most anaerobes require an environment with a low oxidation-reduction potential, which can be achieved in association with low pH, tissue destruction, byproducts from aerobic bacterial metabolism, or low oxygen content. Although they are not true anaerobes, some organisms, such as microaerophilic streptococci and other capnophilic or difficult-to-cultivate bacteria, are sometimes lumped together with anaerobes because of their fastidious nature. Some genera, such as *Lactobacillus* and *Actinomyces*, include both aerobic and anaerobic species. Anaerobic bacteria possess a variety of virulence factors that are species specific (E-Table 273-2).

CLINICAL MANIFESTATIONS

Bacteremia

Transient anaerobic bacteremia occurs in about 85% of patients immediately after dental cleaning or manipulation. An estimated 200 or more cases of endocarditis from anaerobes occur annually in the United States, usually in association with anatomic abnormalities or damaged cardiac valves (Chapter 61). However, most anaerobic bacteremias are intermittent and associated with serious intra-abdominal or female genital tract, skin, and soft tissue infections, often proximal to the gastrointestinal tract. Which organisms are involved depends on their portal of entry and the underlying disease. The most common isolates are the *B. fragilis* group (60 to 75% of isolates). About 3 to 15% of bacteremias are caused by anaerobes, and they are the sole isolates in two thirds of these cases. The most commonly implicated anaerobes in bacteremia are *Cutibacteria*, *B. fragilis*, and *Clostridioides* spp.[1,2] Bacteremia with the *B. fragilis* group generally originates from a gastrointestinal source. Pigmented *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp most commonly originate from oropharyngeal and pulmonary sources, *Fusobacterium* spp usually come from the female genital tract, and *C. acnes* usually from foreign body sources. Bacteremia with peptostreptococci is associated with all sources but especially with the oropharyngeal, pulmonary, and female genital tracts.

Central Nervous System Infections

Anaerobes can cause brain abscess (Chapter 382), subdural empyema (Chapter 382), epidural abscess, and meningitis (Chapter 381). The main source of brain abscess[3] is an adjacent, generally chronic infection in the ears, mastoids, sinuses, oropharynx, teeth, or lungs. Rarely, bacteremia of another origin or endocarditis can cause such infection.

Meningitis caused by anaerobes is uncommon and can follow respiratory or dental infection or develop as a complication of a cerebrospinal fluid shunt. The isolates usually cultured from brain abscesses that complicate respiratory and

routine bacterial cultures were negative,[37] but this test is not commercially available. Magnetic resonance imaging is superior to CT for demonstrating rhombencephalitis.

Specific stool culture is recommended only when routine stool cultures are negative in the setting of an outbreak of gastroenteritis; many people have enteric colonization with *L. monocytogenes* without invasive disease. The laboratory must be advised that listerial infection is suspected because the organism is unlikely to be identified with routine stool culture media. Whole-genome sequencing enhances the real-time detection and investigation of listeriosis outbreaks. Serologic testing (antibody to listeriolysin O) is not useful for invasive disease but may be helpful in the retrospective identification of food-borne outbreaks of febrile gastroenteritis when routine cultures are negative.

Endocarditis, but not bacteremia per se, may be a clue to underlying colon cancer. Colonoscopy should be considered in all cases of listerial endocarditis.

TREATMENT

Because 20% of cases of bacterial meningitis in patients older than age 50 years are due to *L. monocytogenes*, empirical therapy for bacterial meningitis (Chapter 381) in all adults older than age 50 years should include either ampicillin or trimethoprim-sulfamethoxazole, especially in the absence of associated pneumonia, otitis, sinusitis, or endocarditis, which would suggest a cause other than *L. monocytogenes*. Cephalosporins, commonly used for the treatment of bacterial meningitis, should not be used alone when *Listeria* is a diagnostic consideration.

For confirmed cases of listeriosis, ampicillin (2 grams IV every 4 hours) is generally the drug of choice. In cases of meningitis and endocarditis and in patients with severely impaired T-cell function, gentamicin (2 mg/kg IV load and then 1.7 mg/kg every 8 hours, adjusting dose and frequency for renal function and monitoring blood levels to avoid toxicity) is usually added to ampicillin. For meningitis, therapy should be continued for at least 3 weeks; bacteremic patients without CNS involvement may be treated for 2 weeks. Endocarditis and brain abscess should be treated for at least 6 weeks. Meningitis doses should be used to treat all cases of invasive listeriosis, even in the absence of CNS or CSF abnormalities. In patients with penicillin hypersensitivity, trimethoprim-sulfamethoxazole (5 mg/kg trimethoprim component IV every 6 to 8 hours) is the preferred agent and appears to be as effective as the combination of ampicillin and gentamicin. The role of corticosteroids in the treatment of listerial CNS infection is unknown.

Infection of a prosthetic joint usually can be cured only by removing the infected implant. In patients with listeriosis and iron deficiency, it may be prudent to withhold iron replacement until antimicrobial therapy is complete.

PREVENTION

Guidelines for preventing listeriosis are similar to those for preventing other food-borne illnesses: thoroughly cooking raw food from animal sources; washing raw vegetables thoroughly before eating; keeping uncooked meats separate from vegetables and from cooked and ready-to-eat foods; avoiding raw (unpasteurized) milk or foods made from raw milk; and washing hands, knives, and cutting boards after each handling of uncooked foods.

Immunocompromised patients, pregnant women, and the elderly may choose to avoid soft cheeses such as feta, Brie, Camembert, blue-veined, and Mexican-style cheese such as queso fresco. Leftover foods or ready-to-eat foods, such as hot dogs, should be cooked until steaming hot. It is best to avoid foods from delicatessen counters, such as prepared salads, meats, and cheeses.

Listeriosis is effectively prevented by trimethoprim-sulfamethoxazole given as *Pneumocystis* prophylaxis (Chapter 313) to organ transplant recipients, patients who are receiving corticosteroid immunosuppression, or HIV-infected individuals. Except for transmission from infected mother to fetus, human-to-human transmission of listeriosis does not occur, so patients do not need to be isolated.

PROGNOSIS

Listeria meningitis carries an overall mortality rate of about 25%. Listeriosis causes approximately 20 to 30% of all food-borne disease–related deaths. The mortality rate is higher in patients with underlying malignant disease. Mortality from endocarditis and brain abscess is about 50%, and survivors of brain abscess or rhombencephalitis commonly have significant neurologic sequelae.

273 DISEASES CAUSED BY NON–SPORE-FORMING ANAEROBIC BACTERIA

ITZHAK BROOK

DEFINITION

Anaerobic bacteria are the predominant members of the indigenous microbiota, including the skin and the oral, gastrointestinal, and vaginal mucosa (Fig. 273-1; Table 273-1). However, the types of predominant anaerobes differ by location.

The Pathogens

Advances in taxonomics have led to reclassification of many anaerobic species (E-Table 273-1) over the past several decades. *Fusobacterium nucleatum* is the predominant *Fusobacterium* species isolated from clinical specimens.

EPIDEMIOLOGY

Anaerobes are opportunistic pathogens that can cause serious infections, generally synergistic infections in combination with aerobic bacteria. Because the microbiology of these infections is often complex and because culture results may be delayed, awareness of the normal bacterial microbiota at the site of infection is an indispensable guide for the selection and institution of empirical antimicrobial therapy.

PATHOBIOLOGY

Anaerobic bacteria range from those that cannot survive even a brief exposure to oxygen to those that can survive even in the presence of atmospheric oxygen (e.g., *B. fragilis*). Most anaerobes require an environment with a low oxidation-reduction potential, which can be achieved in association with low pH, tissue destruction, byproducts from aerobic bacterial metabolism, or low oxygen content. Although they are not true anaerobes, some organisms, such as microaerophilic streptococci and other capnophilic or difficult-to-cultivate bacteria, are sometimes lumped together with anaerobes because of their fastidious nature. Some genera, such as *Lactobacillus* and *Actinomyces*, include both aerobic and anaerobic species. Anaerobic bacteria possess a variety of virulence factors that are species specific (E-Table 273-2).

CLINICAL MANIFESTATIONS

Bacteremia

Transient anaerobic bacteremia occurs in about 85% of patients immediately after dental cleaning or manipulation. An estimated 200 or more cases of endocarditis from anaerobes occur annually in the United States, usually in association with anatomic abnormalities or damaged cardiac valves (Chapter 61). However, most anaerobic bacteremias are intermittent and associated with serious intra-abdominal or female genital tract, skin, and soft tissue infections, often proximal to the gastrointestinal tract. Which organisms are involved depends on their portal of entry and the underlying disease. The most common isolates are the *B. fragilis* group (60 to 75% of isolates). About 3 to 15% of bacteremias are caused by anaerobes, and they are the sole isolates in two thirds of these cases. The most commonly implicated anaerobes in bacteremia are *Cutibacteria*, *B. fragilis*, and *Clostridioides* spp.[1,2] Bacteremia with the *B. fragilis* group generally originates from a gastrointestinal source. Pigmented *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp most commonly originate from oropharyngeal and pulmonary sources, *Fusobacterium* spp usually come from the female genital tract, and *C. acnes* usually from foreign body sources. Bacteremia with peptostreptococci is associated with all sources but especially with the oropharyngeal, pulmonary, and female genital tracts.

Central Nervous System Infections

Anaerobes can cause brain abscess (Chapter 382), subdural empyema (Chapter 382), epidural abscess, and meningitis (Chapter 381). The main source of brain abscess[3] is an adjacent, generally chronic infection in the ears, mastoids, sinuses, oropharynx, teeth, or lungs. Rarely, bacteremia of another origin or endocarditis can cause such infection.

Meningitis caused by anaerobes is uncommon and can follow respiratory or dental infection or develop as a complication of a cerebrospinal fluid shunt. The isolates usually cultured from brain abscesses that complicate respiratory and

ABSTRACT

Anaerobes are the predominant components of normal human skin and the bacterial flora of mucous membranes. They are a frequent cause of endogenous bacterial infections. Anaerobic infections can occur in all body locations: the central nervous system, oral cavity, head and neck, chest, abdomen, pelvis, skin, and soft tissues. Treatment of anaerobic infection is complicated by their slow growth in culture, by their polymicrobial nature, and by their increasing resistance to antimicrobials. Antimicrobial therapy is frequently the only form of therapy needed, but some anaerobic infections require antibiotics, drainage, and surgery. Because anaerobes generally are mixed with aerobes, the antimicrobial chosen should provide adequate coverage of both.

dental infections include *Prevotella*, *Porphyromonas*, *Bacteroides*, *Fusobacterium*, and *Peptostreptococcus* spp. Microaerophilic and other streptococci are also often isolated. *C. acnes* is common in shunt infections.

Head and Neck

Dental infections (Chapter 393) associated with a variety of oral anaerobes include periodontal disease, gingivitis, pulpitis, acute necrotizing ulcerative gingivitis, localized juvenile periodontitis, adult periodontitis, pericoronitis, endodontitis, periapical and dental abscesses, and postextraction infection. Peritonsillar, retropharyngeal, and parapharyngeal abscesses (Chapter 397) are deep-seated, potentially life-threatening infections that may spread into the various potential spaces of the neck or mediastinum and cause jugular vein thrombosis. Oral anaerobes can be recovered in more than 50% of such cases, usually mixed with aerobes. Other regional infections include cervicofacial actinomycosis (Chapter 304), Ludwig angina, *Fusobacterium necrophorum* sepsis with metastatic infection (Lemierre syndrome; Chapter 397),[4] suppurative sialoadenitis (including parotitis), neck space infections, thyroiditis and chronic sinusitis (Chapter 394), otitis media (Chapter 394), and mastoiditis.

Pleuropulmonary

Anaerobes predominate in oral and upper respiratory tract normal flora, and most aspiration pneumonias[5] are due to these flora (Chapter 85). Aspiration can result from altered consciousness, dysphagia, or mechanical devices such as intubation equipment. Poor oral hygiene is associated with an increased anaerobic bacterial burden, and the presence of aerobes or necrotic tissue lowers the pH, which facilitates the growth of anaerobes. Anaerobes are involved in 90% of community-acquired aspiration pneumonia and in about a third of nosocomial aspiration pneumonia, empyema, lung abscess (Chapter 78), and pneumonia associated with tracheostomy (Chapter 85).

Intra-abdominal

Because anaerobes outnumber aerobes by 1000 to 1 in the large intestine, they play a major role in almost all intra-abdominal infections. Most visceral abscesses (e.g., hepatic; Chapter 137), chronic cholecystitis (Chapter 141), perforated and gangrenous appendicitis (Chapter 128), postoperative wound infections and abscesses, diverticulitis (Chapter 128), and any infection associated with fecal contamination of the abdominal cavity involve both aerobes and anaerobes. *B. fragilis* group members predominate because they are encapsulated, resist phagocytosis, are often resistant to many antimicrobials, and promote abscess formation. They also may be associated with concomitant bacteremia and sepsis.

Obstetric-Gynecologic

A variety of obstetric-gynecologic infections involve anaerobes. These are polymicrobial and include bacterial vaginosis; soft tissue perineal, vulvar, and Bartholin gland abscesses; endometritis; pyometra; salpingitis; tubo-ovarian abscesses; adnexal abscess; pelvic inflammatory disease (Chapter 264), which may include pelvic cellulitis and abscess; chorioamnionitis; vaginal cuff cellulitis; septic pelvic thrombophlebitis; intrauterine contraceptive device–associated infection; septic abortion; and postsurgical obstetric and gynecologic infections. Bacterial vaginosis has been associated with preterm labor or delivery, chorioamnionitis, low birthweight, postpartum endometritis, and postabortal pelvic inflammatory disease. Bacterial vaginosis can increase the risk for infection with human immunodeficiency virus (Chapter 353) and the development of other sexually transmitted diseases (Chapter 264).

Skin and Soft Tissue

Cutaneous infections include infected ulcers, cellulitis (including synergistic necrotizing cellulitis; Chapter 408), pyoderma, paronychia, hidradenitis suppurativa, and a variety of secondarily infected sites. Such sites include secondarily infected gastrostomy or tracheostomy site wounds, subcutaneous sebaceous or inclusion cysts, eczema, psoriasis, poison ivy, atopic dermatitis (Chapter 405), eczema herpeticum, scabies (Chapter 98) or kerion, and postsurgical wounds.

Subcutaneous infections include abscesses, decubitus ulcers, infected diabetic (vascular or trophic) ulcers (Chapter 210), human and animal bite wounds, anaerobic cellulitis and gas gangrene, bacterial synergistic gangrene, Fournier gangrene,[6] infected pilonidal cyst or sinus, and burn wounds (Chapter 97). Anaerobic soft tissue infections that occur deeper are necrotizing fasciitis, necrotizing synergistic cellulitis, and gas gangrene. These infections can involve the fascia and can induce myositis and myonecrosis.

TABLE 273-1 LOCATION OF VARIOUS GROUPS OF ANAEROBES AS NORMAL MICROFLORA IN HUMANS

LOCATION	NO. OF ORGANISMS PER GRAM		PREDOMINANT ANAEROBIC BACTERIA
	AEROBES	ANAEROBES	
Skin	—	—	*Cutibacterium acnes* *Peptostreptococcus* spp
Mouth/upper respiratory tract (in saliva)	10^8-10^9	10^9-10^{11}	Pigmented *Prevotella* and *Porphyromonas* spp *Fusobacterium* spp *Peptostreptococcus* spp *Actinomyces* spp
Gastrointestinal tract (in fecal material)

Lower	10^5-10^9	10^{10}-10^{12}	*Peptostreptococcus* spp *Bifidobacterium* spp *Eubacterium* spp
Female genital tract (in vaginal secretions)	10^8	10^9	*Peptostreptococcus* spp *Prevotella bivia* *Prevotella disiens*

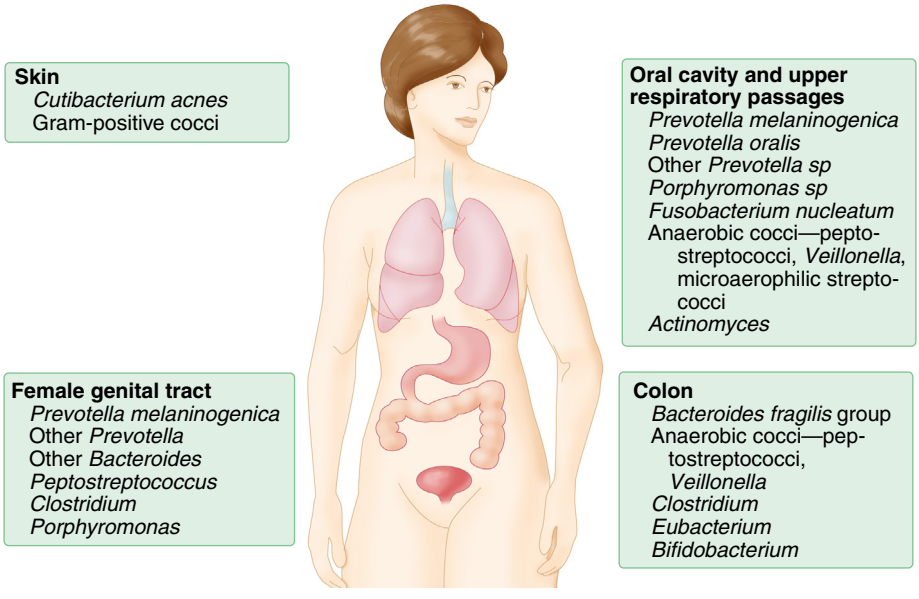

FIGURE 273-1. Anaerobes as the predominant normal microbiota of the human body by general anatomic location. (Modified from Finegold SM, Sutter VL. *Diagnosis and Management of Anaerobic Infections*. Kalamazoo, MI: Upjohn; 1976.)

Cultures of skin and soft tissue infections frequently yield isolates that are members of the normal flora of the region of the infection. In addition to oral and skin flora, human bite infections often contain *Eikenella* species, and animal bites harbor *Pasteurella multocida*. Skin infections are generally polymicrobial, and some (e.g., decubitus ulcers, diabetic foot ulcers) are often complicated by osteomyelitis or bacteremia. Deep tissue infections, such as necrotizing cellulitis, fasciitis, and myositis, often involve *Clostridioides* species (Chapter 271), *Streptococcus pyogenes* (Chapter 269), or a polymicrobic aerobic and anaerobic flora; they are often associated with gas in the tissues and putrid-like pus with a gray, thin quality and have a high rate of bacteremia and mortality.

Osteomyelitis and Septic Arthritis

Anaerobes can be involved in osteomyelitis (Chapter 251) of the long bones after trauma and fracture, osteomyelitis related to peripheral vascular disease, decubitus ulcers, and osteomyelitis of the cranial and facial bones. Most of these infections are polymicrobial.

Cranial and facial bone osteomyelitis is generally caused by spread from a contiguous soft tissue source or from sinus, ear, or dental infection. Intestinal anaerobes originating from decubitus ulcers (Chapter 407) are involved in pelvic osteomyelitis. Osteomyelitis of long bones and septic arthritis are generally caused by hematogenous spread, trauma, or the presence of a prosthetic device. The most commonly recovered anaerobes are peptostreptococci and *C. acnes* (often in prosthetic joint infection), *B. fragilis* group and fusobacteria (often of hematogenous origin), and clostridia (associated with trauma).

DIAGNOSIS

Anaerobic infections should be suspected in a number of specific clinical scenarios (Table 273-2). An appropriately collected microbiologic specimen (Table 273-3) is critical for accurate diagnosis. Anaerobic bacteremia is associated with a substantially increased risk of colorectal cancer,[7] so an appropriate evaluation is indicated unless the patient has an obvious other source.

TABLE 273-2 CLINICAL INDICATORS OF ANAEROBIC INFECTION

Infection adjacent to a mucosal surface
Foul-smelling discharge
Necrotic gangrenous tissue and abscess formation
Free gas or crepitus in tissue
Bacteremia or endocarditis with no growth on aerobic blood cultures
Infection related to the use of antibiotics effective against aerobes only (e.g., trimethoprim-sulfamethoxazole, aminoglycosides, older quinolones)
Infection related to tumors or other destructive processes
Infected thrombophlebitis
Infection after bites
Black discoloration of exudates containing *Prevotella melaninogenica*, which may fluoresce under ultraviolet light
"Sulfur granules" in discharges caused by actinomycosis
Clinical finding of gas gangrene or necrotizing fasciitis
Clinical condition predisposing to anaerobic infection (e.g., after maternal amnionitis, fistulous tracks, bites, dental infection, bowel perforation)

TABLE 273-3 SPECIMEN ACCEPTABILITY FOR ANAEROBIC CULTURE

SPECIMENS THAT SHOULD NOT BE CULTURED FOR ANAEROBES
Feces or rectal swabs
Throat or nasopharyngeal swabs
Sputum or bronchoscopic specimens
Routine or catheterized urine
Vaginal or cervical swabs
Material from superficial wounds or abscesses not collected properly to exclude surface contamination
Material from abdominal wounds obviously contaminated with feces, such as an open fistula
SPECIMENS APPROPRIATE FOR ANAEROBIC CULTURE
All normally sterile body fluids other than urine, such as blood, pleural fluid, and joint fluid
Urine obtained by suprapubic bladder aspiration
Percutaneous transtracheal aspiration, direct lung puncture, or double-lumen catheter bronchial brushing and bronchoalveolar lavage (both cultured quantitatively)
Culdocentesis fluid obtained after decontamination of the vagina
Material obtained from closed abscesses
Material obtained from sinus tracks or draining wounds

TREATMENT

General principles of treatment (Table 273-4) include appropriate antimicrobial therapy coupled with prompt drainage, decompression of closed space infections, relief of obstructions, and surgical débridement. The various clinically important anaerobes can be characterized by reasonably predictable antimicrobial susceptibility patterns (Table 273-5). However, some anaerobes have become resistant to antimicrobials,[8] and many can develop resistance during therapy. Reliable culture and sensitivity results should ultimately guide therapy. The efficacy of hyperbaric oxygen is unproven, but its use in conjunction with other therapeutic measures may be beneficial.

In choosing antimicrobials for the treatment of mixed infections, their aerobic and anaerobic antibacterial spectra and their availability in oral or parenteral form should be considered. Some antimicrobials have a limited range of activity. For example, metronidazole is active only against anaerobes and therefore cannot be administered as a single agent for the treatment of mixed infections. Others (i.e., carbapenems, a penicillin plus a β-lactamase inhibitor) have wide spectra of activity against aerobes and anaerobes.

Aside from susceptibility patterns, other factors influencing the choice of antimicrobial therapy include the pharmacologic characteristics of the various drugs, their toxicity, their effect on normal flora, and their bactericidal activity. Although identification of the infecting organisms and their antimicrobial susceptibility may be needed for selection of optimal therapy, the clinical setting and Gram stain preparation of the specimen may suggest the types of anaerobes present in the infection and the nature of the infectious process.

Even though the length of therapy for anaerobic infections is generally longer than that for aerobic and facultative infections, the length of treatment must be individualized, depending on the response. In some cases, treatment may require 6 to 8 weeks, but therapy may be shortened with proper surgical drainage. For example, management of head and neck anaerobic infection usually requires surgical drainage as well as appropriate antimicrobial therapy. An anti–gram-negative enteric agent is generally added to treat Enterobacteriaceae in managing intra-abdominal infections.

The available parenteral antimicrobials for most infections are metronidazole, chloramphenicol, clindamycin, cefoxitin, a penicillin (e.g., ticarcillin, ampicillin, piperacillin) and a β-lactamase inhibitor (e.g., clavulanic acid, sulbactam, tazobactam), a carbapenem (e.g., imipenem, meropenem, doripenem, ertapenem), and tigecycline. Resistance is emerging against clindamycin, cefoxitin, cefotetan, and moxifloxacin in the *B. fragilis* group.

An agent effective against gram-negative enteric bacilli (e.g., an aminoglycoside, fluoroquinolone) or an antipseudomonal cephalosporin (e.g., cefepime) is generally added to metronidazole and, occasionally, cefoxitin in the treatment of intra-abdominal infections. In one randomized trial of adult patients with complicated intra-abdominal infections, including infections caused by multidrug-resistant pathogens, treatment with ceftolozane/tazobactam plus metronidazole was equivalent to meropenem.[A1] By comparison, adding metronidazole to ceftriaxone and doxycycline reduces pain but does not clearly improve outcomes.[A2] Penicillin can be added to metronidazole for the treatment of intracranial, pulmonary, or dental infections to cover microaerophilic streptococci and *Actinomyces* species. Penicillin is added to clindamycin to supplement its coverage against *Peptostreptococcus* species and other gram-positive anaerobic organisms.

For *Chlamydia* and *Mycoplasma* species, doxycycline is added to most regimens in treatment of pelvic infections. Oral therapy is often substituted for parenteral therapy. The agents available for oral therapy are clindamycin, amoxicillin and clavulanate, and metronidazole.

If the anaerobic component of aspiration pneumonia is not treated, the anaerobes can cause a lung abscess (Chapter 78). Management requires good pulmonary toilet and antimicrobial therapy. Management of deep-seated soft tissue infection includes surgical débridement, drainage, and vigorous surgical management.

TABLE 273-4 GENERAL PRINCIPLES OF THERAPY FOR ANAEROBIC INFECTIONS

Decompression of closed spaces
Débridement
Drainage
Relief of obstructions
Irrigation
Provision of adequate circulation when possible
Removal of foreign bodies
Antimicrobials
Activity against most likely pathogen or pathogens: location dependent, minimal effect on normal flora
Absorption, appropriate route of administration (intravenous, oral)
Penetration into site of infection
Dosage appropriate for local tissue levels, body mass of patient, renal and liver function
Duration appropriate for condition
Susceptibility testing of isolate to guide specific therapy

Antimicrobials can be administered parenterally or orally in the recommended doses (see Table 266-4), with durations of treatment depending on the clinical response, typically with expert consultation.
+ = susceptible; – = resistant; V = variable.

PREVENTION

Randomized trials have shown that prophylactic antibiotics covering both anaerobic and aerobic bacteria administered intravenously before elective colorectal surgery and briefly orally thereafter reduce the risk of surgical wound infection by as much as 75%.[A3]

PROGNOSIS

Anaerobic infections usually respond to appropriate therapy. However, mortality associated with *B. fragilis* group bacteremia is 15 to 30%.

274 *NEISSERIA MENINGITIDIS* INFECTIONS

DAVID S. STEPHENS

DEFINITION

Neisseria meningitidis (the meningococcus) is the cause of epidemic bacterial meningitis, fulminant sepsis (meningococcemia), milder bacteremia, and, less commonly, focal infections (such as pneumonia, septic arthritis, purulent pericarditis, urethritis, and conjunctivitis).

The Pathogen

N. meningitidis is an aerobic, diplococcal gram-negative β-proteobacterium and a member of the family Neisseriaceae, which also includes *Neisseria gonorrhoeae* (Chapter 275), the cause of gonorrhea. The meningococcus is a frequent commensal of the human upper respiratory tract but can also cause local and devastating invasive human disease. Human mucosal surfaces, most commonly the nasopharynx but sometimes the rectum and urogenital tract, are the important reservoirs. In addition to commensal unencapsulated meningococci, there are 12 confirmed serogroups of *N. meningitidis*, based on different capsular polysaccharide structures. However, only 6 groups (A, B, C, W, X, and Y) cause almost all invasive meningococcal disease globally (Fig. 274-1). Highly pathogenic meningococci are also distinguished by capsule expression and by genetically defined clonal complexes and genotypes that can emerge and spread worldwide.

EPIDEMIOLOGY

The meningococcus can cause sporadic disease, case clusters, epidemics, and pandemics of meningitis and septicemia and less commonly of pneumonia and other local infections. In the pre-vaccine era, an estimated 500,000 to 1 million cases occurred worldwide each year, but the incidence has been dramatically lowered, related to the widespread use of vaccines.[1] The greatest burden of disease is in sub-Saharan Africa, where endemic rates of disease have been 3 to 10 per 100,000 population, but rates were 1 per 1000 population during the historic cyclic pandemics that occurred every 8 to 10 years. The introduction in 2010 of a new meningococcal conjugate vaccine for group A (MenAfriVac) eliminated group A outbreaks in the region, but less severe outbreaks of group C, X, and W continue.[2]

Overall incidence has declined, aided by the expanded use of the meningococcal ACWY conjugate and group B directed vaccines,[3] and the decline has been accelerated by containment measures for severe acute respiratory syndrome coronavirus 2 (SARS-CoV2; Chapter 336). Nevertheless, meningococcal disease remains sporadic[4] (incidence less than 0.1 to 2 per 100,000 population), with focal outbreaks/clusters in the United States, Canada, Mexico, Europe, Japan, Australia, China, Russia, South America (Chile, Brazil, Argentina), India, Southeast Asia, and other countries. Organization-based and university outbreaks are mostly caused by group B, whereas group C is the primary cause of community-based outbreaks. Meningococcal disease has its highest incidence in children below age 4 years (often group B) and in adolescents; but in sporadic settings, half of all cases occur in adults.

Asymptomatic carriage in the oropharynx is much more common (about 7-10% among adolescents ages 15 to 19 years in developed countries) than symptomatic infection, and the prevalence of meningococcal carriage is declining in many populations.[5] Asymptomatic carriage has been linked to social

ABSTRACT

The human bacterial pathogen *Neisseria meningitidis* remains a cause of meningitis, sepsis, and focal infections (pneumonia, septic arthritis, purulent pericarditis urethritis, conjunctivitis) worldwide, but effective vaccines are improving global control. An asymptomatic carrier state is found in 8 to 25% of healthy individuals, often with unencapsulated strains or strains with low virulence. Most meningococcal disease is caused by encapsulated meningococci of groups A, B, C, W, Y, and X expressed by several hypervirulent genomic clonal complexes. Predisposing factors for systemic meningococcal disease include absence of protective bactericidal antibodies (young children), complement component deficiencies (congenital or acquired, such as individuals treated with the complement inhibitor eculizumab), and congenital or acquired antibody deficiencies. Mortality remains approximately 10% for invasive meningococcal disease, and long-term sequelae are significant in 10 to 20% of survivors. Early recognition and antibiotic therapy (e.g., ceftriaxone) are central for effective treatment of invasive meningococcal disease. Prevention of disease in close contacts is accomplished with chemoprophylaxis. Vaccines are effective to prevent disease from groups A, C, W, Y, B, and soon X in at-risk populations.

FIGURE 274-1. Epidemiology of meningococcal disease (2022 global distribution of major capsular groups causing disease by region). (Modified from Stephens DS, Greenwood B, Brandtzaeg P. Epidemic meningitis, meningococcemia, and *Neisseria meningitidis*. *Lancet*. 2007;369:2196-2210.)

behavior (e.g., attendance at pubs or clubs, intimate kissing, cigarette smoking, or exposure to passive smoke). Carriage, which can be transient or persist for days, weeks, or months, is an immunizing event leading to protective immunity (e.g., serum bactericidal activity against the meningococcus).

PATHOBIOLOGY

N. meningitidis is transmitted among humans through close contact by large respiratory droplets or saliva. Colonization of the upper respiratory or other mucosal surfaces (e.g., nasopharynx) by *N. meningitidis* is the first step in establishing a human carrier state. Acquisition of meningococci through contact with secretions can be transient, lead to prolonged nasopharyngeal carriage, or result in invasive disease. The inoculum size needed for transmission is unknown. Invasive meningococcal disease usually occurs within 1 to 14 days after acquisition. Meningococci can also spread from the nasopharynx to adjacent epithelial surfaces, where they infrequently cause local infections, including pneumonia, sinusitis, and otitis media. Meningococci also can be found in the conjunctivae, urogenital tract, and rectum, and they may be transmitted sexually.[6]

Initial contact of meningococci with mucosal epithelial cells is mediated by type IV pili. These structures provide mobility ("twitching motility") to penetrate mucus and are the initial adhesins for human epithelial cells. Meningococci proceed to proliferate and form small microcolonies on the surface of human nonciliated epithelial cells. They can disseminate from colonies by post-translational glycan modifications of pili and migrate to adjacent cells by the pili-mediated motility. Close adherence of meningococci to the host epithelial cells results in the formation of epithelial cell cortical plaques and leads to the recruitment of factors ultimately responsible for the formation and extension of host epithelial cell pseudopodia that can tightly bind the meningococcus. Intimate meningococcal association with the epithelial cell is mediated by the meningococcal surface components, including opacity proteins Opa and Opc with CD66/carcinoembryonic antigen–related cell adhesion molecules and integrins, respectively, on the surface of the human cell. Other meningococcal epithelial cell mediators include the meningococcal adhesin NadA and meningococcal lipo-oligosaccharide. The formation of epithelial cell membrane protrusions and pseudopodia stems from the organization of specific molecular complexes involving the linkers ezrin and moesin along with the clustering of several membrane-integral proteins, including CD44, intracellular adhesion molecule 1, and cortical actin polymerization. These events can lead to internalization of *N. meningitidis* in epithelial cells (E-Fig. 274-1). Intracellular meningococci reside within a membranous vacuole and are capable of translocating across the epithelial layer. Meningococci are capable of intracellular replication (in part because of the protective capsule), can survive under microaerophilic conditions, use lactate as a carbon source, and have the capacity to acquire iron through specialized transport systems.

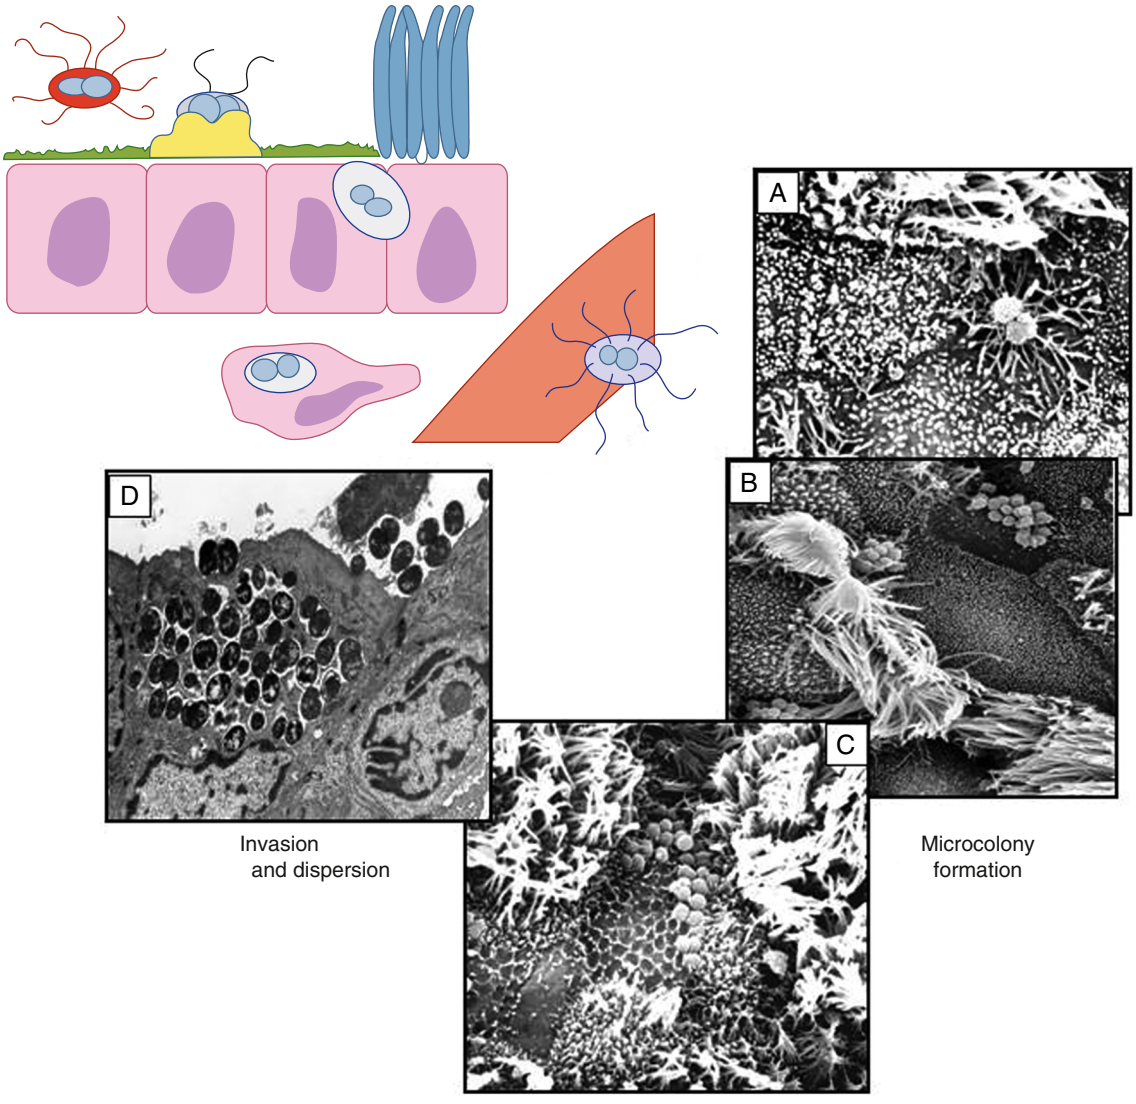
Damage to the mucosal surface by coinfections, drying (e.g., very low humidity), or smoke exposure may increase the risk for meningococcal carriage and invasion. Meningococci may cross mucosal surfaces, enter the blood stream to cause bacteremia, and, in some individuals, produce systemic infections. Asymptomatic meningococcal carriage also has been linked to status as a secretor of glycoprotein ABO blood group antigens, which are water soluble. Similar molecular interactions noted for meningococci and epithelial cells also occur with endothelial cells, and meningococci can translocate across the blood-meninges barrier, possibly at the choroid plexus or by the opening of intercellular junctions, and proliferate in the subarachnoid space, thereby causing meningitis. In the vasculature and cerebrospinal fluid (CSF), high levels of multiplying bacteria lead to an intense inflammatory response, with pronounced increases in concentrations of tumor necrosis factor-α, interleukins (1β, 6, 8, and 10), other chemokines, and inflammatory mediators.

Meningococcal resistance to complement-mediated lysis or phagocytosis is due to the expression of the capsule, lipo-oligosaccharide, and several surface-exposed proteins (factor H–binding protein, NspA, Opc, NalP). Meningococcal endotoxin released in blebs plays a major role in the inflammatory events of meningococcemia and meningococcal meningitis. Meningococcal lipid A is responsible for much of the biologic activity and toxicity of meningococcal endotoxin. Activation of toll-like receptor 4 (TLR-4) by endotoxin requires association with the accessory protein MD-2, an *N*-glycosylated 19- to 27-kD protein expressed in both a soluble and a membrane-bound form. Binding of endotoxin to MD-2 in association with TLR-4 leads to dimerization or oligomerization of two or more TLR-4s, subsequent cellular activation, and cytokine and chemokine release.

The absence of protective bactericidal antibodies is the most important predisposing risk factor for systemic meningococcal disease, but complement deficiencies (congenital or acquired such as with the complement inhibitors eculizumab and ravulizumab [Chapter 29]), genetic polymorphisms, and other host cofactors can contribute to meningococcal disease and disease severity. Disappearance of protective maternal antibodies increases the risk in older infants and young children. Congenital and acquired antibody deficiencies also increase risk. Opsonization and phagocytic function also contribute to meningococcal host defense mechanisms, as shown by disease reduction after meningococcal vaccination in individuals with terminal complement deficiencies (Chapter 37).[7] Rapidly progressive, fatal meningococcemia can arise in patients without properdin, and there is a marked risk for recurrent meningococcal infections in individuals with defects in the terminal complement pathway (C5-C9) and C3 deficiency.

Polymorphisms in genes coding for the Fcγ-receptor II (CD32), Fcγ-receptor III (CD16), mannose-binding lectin, TLR-4, and the β_2-adrenoceptor gene have been associated with increased risk. Plasminogen activator inhibitor 1 concentrations appear to affect the severity and mortality of meningococcal sepsis, thereby suggesting that impaired fibrinolysis is an important factor in its pathophysiology. Meningococcal disease is also linked to immunosuppressive disorders, such as nephrotic syndrome (Chapter 107), congenital or acquired hypogammaglobulinemia (Chapter 231), splenectomy, and human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS; Chapter 358) (about a 10-fold increased risk for sporadic meningococcal disease). However, there has not been a documented increase in epidemic outbreaks of meningococcal disease in countries with high rates of HIV infection.

Meningococci can multiply rapidly in the vascular compartment, with an estimated doubling time of 30 to 45 minutes in some patients, or in the CSF. The release of high levels of inflammatory mediators such as meningococcal



E-FIGURE 274-1. **Steps in initiation of meningococcal colonization and invasion at the human nasopharynx. endotoxin in the circulation or CSF triggers an exaggerated release of chemokines, cytokines, bradykinin, and nitric oxide. Vascular dilation, hypovolemia, capillary leak, and pronounced reduction in myocardial function are the result. At a later stage, substantial complement activation contributes to the altered endothelial barrier function and relaxation of the smooth muscles in the vessel wall through the generation of high levels of anaphylatoxins (C3a and C5a). The capillary leak syndrome results in an increased flux of albumin and water across the altered capillary wall to the extravascular space. Circulatory collapse and multiorgan dysfunction are the primary causes of death due to meningococcemia. In meningitis, morbidity and death are due predominantly to cerebral edema.

CLINICAL MANIFESTATIONS

The meningococcus causes meningitis (37 to 50% of invasive cases), septicemia (meningococcemia, 10 to 18% of cases), or both (7 to 12% of cases). Less common presentations are a mild bacteremia or pneumonia (10% of cases) and, in less than 5% of cases, septic arthritis, pericarditis, chronic bacteremia, or conjunctivitis. Meningococci can cause urethritis or proctitis. In endemic and epidemic disease outbreaks, hemorrhagic skin lesions (petechiae, purpura; Fig. 274-2) are present in about 25 to 75% of patients with meningococcal disease on admission, but these lesions may be absent or difficult to see in patients with dark skin. Hemorrhagic lesions sometimes occur on mucous membranes and sclerae, but they are especially prevalent on the limbs. The petechiae of meningococcemia are usually larger and bluer than the pinpoint petechiae caused by thrombocytopenia or leukocytoclastic vasculitis induced by other infections or drugs. A nonblanching macular rash also can be a manifestation of meningococcal bacteremia. Evolving ecchymoses and purpura (diameter >10 mm) are noted mainly in patients with meningococcemia and disseminated intravascular coagulation (Chapter 161), but they may not appear until 12 hours into the illness. In addition to vasculitis, other conditions in the differential diagnosis of meningococcemia include Rocky Mountain spotted fever (Chapter 302) and enteroviral infections (Chapter 349).

Meningitis (Chapter 381) is the most common clinical presentation of invasive meningococcal disease.[8] Headache, fever, and rash with meningismus and altered mental status are the characteristic features; however, the rash may be absent, and the presentation can resemble pneumococcal or bacterial meningitis of other causes, viral meningitis, or early-stage encephalitis. Bacteremic meningococcal pneumonia has been linked more often to groups Y and W and is more common in adolescents and adults, especially older adults (approximately one third of cases occur in patients older than 65 years). Acute presentations also include isolated septic pericarditis or septic arthritis, and autoimmune- or antibody-mediated polyarthritis can be seen in the recovery phase following invasive meningococcal disease. Chronic meningococcemia can be manifested with low-grade fever and a polyarticular arthritis that can be confused with rheumatoid arthritis.

In contrast to invasive disease, an asymptomatic *N. meningitidis* carrier state is found in up to 8 to 25% of healthy individuals. Meningococcal carriage rates are affected by age, intimate personal contact, crowding (e.g., bars, dormitories), and vaccination or chemoprophylaxis interventions in the community. Variable carriage rates have been reported, even during epidemics. Meningococcal carriage is a dynamic process, is less common in young children (<3% and *Neisseria lactamica* predominates) than in older children, is highest in adolescents (7 to 37%), and increases in closed populations (e.g., military recruits, Hajj pilgrims),[9] with rates as high as 35 to 70% reported in military recruits.

DIAGNOSIS

The clinical diagnosis of meningococcal meningitis relies on the recognition of fever, rash, meningeal signs, and altered mental status. The early clinical diagnosis of meningococcemia is a challenge because a rash, meningeal signs, and high fever may not be present. General symptoms of sepsis (nausea and vomiting, drowsiness, irritability, leg pains, cold hands and feet, abnormal skin color) are present, but these symptoms and signs are not specific, and the early stages of disease can mimic viral infections such as those caused by enteroviruses (Chapter 349) or influenza (Chapter 332). Parents and relatives should be instructed to undress and inspect a febrile patient for a rash. The course can be fulminant (<24 hours), so physicians must be alert to any rapid clinical deterioration.

The definitive diagnosis of invasive meningococcal disease is based on bacteriologic isolation or identification of *N. meningitidis* DNA or antigen in a usually sterile body fluid, such as blood, CSF, synovial fluid, pleural fluid, urine, or pericardial fluid. Polymerase chain reaction (PCR) testing, which is increasingly the assay of choice for the diagnosis of meningococcal disease,

FIGURE 274-2. Clinical manifestations of meningococcal disease. A and B, Macular and petechial rashes of meningococcal bacteremia. **C,** Fulminant meningococcal sepsis with ecchymoses. **D,** Digital necrosis of meningococcemia sepsis. **E,** Hemorrhagic adrenals in fulminant meningococcal sepsis. (Modified from Stephens DS, Greenwood B, Brandtzaeg P. Epidemic meningitis, meningococcemia and *Neisseria meningitidis*. *Lancet*. 2007;369:2196-2210.)

can identify serogroups and has the potential to detect antibiotic resistance.[10] The sensitivity of PCR for the diagnosis of meningococcal meningitis is 90 to 95%; in contrast, the sensitivity of CSF or blood culture (often because of prior antibiotic administration) is less than 65%, and skin and urine are even less sensitive sites.

Blood and CSF are the most fruitful sources of positive cultures and for DNA identification by the PCR, but urine and skin lesions can also yield results in systemic meningococcal disease. The diagnosis of meningococcal meningitis is confirmed by CSF pleocytosis, Gram stain showing gram-negative diplococci (often inside neutrophils), CSF culture, PCR identifying *N. meningitidis* in CSF, or latex agglutination detecting meningococcal capsular polysaccharide in CSF. However, an increasing number of patients are now diagnosed by PCR without culture, especially if they have received empirical prehospital antibiotic treatment. Whole genome sequencing is being increasingly used as an epidemiologic and organism confirmation tool.

TREATMENT

Early recognition and administration of antibiotics (Table 274-1) are critical for successful treatment, because effective antibiotics immediately stop the growth of *N. meningitidis*.[11] Ceftriaxone and cefotaxime, which can achieve CSF concentrations 45- to 8750-fold higher than the minimal inhibitory concentrations for meningococci, are the most effective antibiotics, but meropenem is also effective in most cases.[12] Chloramphenicol is an alternative in patients who are allergic to penicillin and cephalosporins. The sensitivity of meningococci to penicillin is decreasing worldwide because of a reduced affinity for penicillin-binding protein 2 and the emergence of beta-lactamase–producing meningococci. Fluoroquinolones and aztreonam are potential alternatives, but data on meningococcal disease are limited, and fluoroquinolone-resistant meningococci have become more prevalent. First-generation cephalosporins should not be used.

Meningococci in CSF are killed within 3 to 4 hours after intravenous treatment with an adequate dose of a third-generation cephalosporin, and concentrations of endotoxin in plasma fall by 50% within 2 hours. The concentrations of key cytokines and chemokines fall in parallel. Antibiotic treatment does not induce a large release of meningococcal endotoxin or lead to an increased inflammatory response. Intravenous treatment for 3 or 4 days can provide a cure without relapse.

Prehospital antibiotic treatment is advocated if the disease is suspected. The goal is to reduce the case-fatality rate for patients with fulminant meningococcal sepsis or meningitis with rapidly increasing concentrations of meningococci and inflammatory mediators in the circulation or CSF. If antibiotic treatment is initiated before admission, ceftriaxone or another effective antibiotic can be injected intravenously or intramuscularly. During epidemics in developing countries, a single injection of ceftriaxone or long-acting chloramphenicol may be sufficient for patients with meningitis, and this simple treatment has saved many thousands of lives.

Patients with suspected bacterial meningitis of unknown cause are often given intravenous ceftriaxone or cefotaxime, often combined with vancomycin, until the causative agent has been identified. When *N. meningitidis* is identified, antibiotic treatment can be continued with an antibiotic to which it is highly sensitive.

TABLE 274-1 ANTIBIOTIC TREATMENT OF MENINGOCOCCAL MENINGITIS AND MENINGOCOCCEMIA

DRUG	AGE GROUP	DOSAGE
Ceftriaxone*	Children >3 months	50 mg/kg IV q12h
	Adults	1-2 g IV q12h
Cefotaxime	Adults	50-75 mg/kg IV q6-8h; maximum dose, 12 g/day
Meropenem	Adults	2 g IV q8h, 6 g/day
Penicillin G†	Adults	50,000 U/kg IV q4h; up to 4 million U q4h
If penicillin and cephalosporin allergic, chloramphenicol†	Adults	25 mg/kg IV q6h, up to 1 g q6h

*Because of concerns in neonates from calcium/ceftriaxone precipitates and displacement of bilirubin from albumin by ceftriaxone, babies younger than 3 months should be started on cefotaxime 50 mg/kg q6-8h.
†Use only if isolate found to be susceptible to penicillin.
‡Aztreonam or fluoroquinolones are potential alternatives.
IV = intravenous; q = once every.

Adjunctive Therapy

Meningococcemia

For meningococcal sepsis, early and aggressive management of shock can reduce case-fatality rates of meningococcal sepsis from higher than 30% to 5 to 10%. In meningococcemia with hypotension, aggressive fluid treatment starts with 1 L saline infused intravenously during 15 to 20 minutes, followed by several liters at a reduced rate. Some patients require two to three times their own blood volume during the first 24 hours. Fluid treatment may need to be combined with a vasopressor (see Chapter 94), while monitoring and correcting acidosis, hypoglycemia, hypokalemia, hypocalcemia, and hypomagnesemia.

Patients with fulminant meningococcal septicemia can develop adrenal hemorrhage (Waterhouse-Friderichsen syndrome). The corticotropin concentration is higher, the cortisol concentration is lower, and the corticotropin-to-cortisol ratio is higher in patients with fatal meningococcal shock than in survivors. Adults with septic shock and indications of inadequate adrenal function should be given low doses of steroids (e.g., hydrocortisone 50 mg intravenously over 6 hours, four times daily for 7 days).

Anticoagulant treatment of patients with meningococcemia and disseminated intravascular coagulation does not improve outcomes, nor does using hyperimmune serum, antibodies, blockade of inflammatory mediators, or recombinant bactericidal or permeability-increasing protein (designed to inactivate *N. meningitidis* endotoxin). Plasmapheresis, blood exchange, and extracorporeal membrane oxygenation have been used in patients with meningococcemia, but no controlled trials have been done. Extracorporeal membrane oxygenation has been tried in several centers.

Meningococcal Meningitis

Patients with meningitis without shock should be given the normal daily fluid requirement, supplemented with the volume lost before admission unless there is evidence of the syndrome of inappropriate antidiuretic hormone (Chapter 102). Excessive volume treatment in patients with meningitis can induce fatal brain edema and herniation. Management of raised intracranial pressure (hyperosmolar solutions, diuretics, mechanical ventilation), seizures, and hyponatremia in neurointensive care is indicated.

Pharmacologic doses of dexamethasone reduce hearing loss in pneumococcal and *Haemophilus influenzae* type b meningitis (Chapter 381).[A1] However, the benefit of dexamethasone to reduce death or to prevent other sequelae in patients with meningococcal meningitis remains unproven on the basis of large randomized controlled trials, even though trends toward reductions in hearing loss, mortality, and arthritis after meningococcal disease are reported. Many experts recommend that dexamethasone (10 mg every 6 hours; 0.15 mg/kg every 6 hours in children) be given for 4 days beginning before (for maximal efficacy) or with the first dose of antibiotics in suspected or confirmed bacterial meningitis.

Other Complications

Other major life-threatening complications requiring intervention include acute respiratory distress syndrome (Chapter 90), neurologic sequelae ranging from coma (Chapter 373) to diabetes insipidus (Chapter 206), pneumonia that is not necessarily meningococcal but may be secondary to aspiration during the obtunded state (Chapter 373), and purulent pericarditis (Chapter 62) with tamponade.

Immune complex–mediated complications, such as arthritis, cutaneous vasculitis, iritis, episcleritis, pleuritis, and pericarditis, can first appear several days to 2 to 3 weeks after onset of illness, when the patient is otherwise improving. These complications, which can be multiple, are due to the deposition of antigen-antibody complexes composed of meningococcal capsular polysaccharide or other antigens, meningococcal-specific immunoglobulins, and C3. They complicate 6 to 15% of cases of meningococcal meningitis or septicemia. Treatment is with typical doses of aspirin or nonsteroidal anti-inflammatory drugs, and resolution is complete, usually within 14 days from the onset and usually without residual sequelae.

PREVENTION

The occurrence of meningococcal disease in household contacts is approximately 100-fold higher than in the general population. Secondary cases usually occur within 1 to 14 days of the primary case. Chemoprophylaxis (Table 274-2), which is recommended for close contacts of patients to prevent further transmission and disease, eliminates meningococcal carriage and can be helpful to control localized outbreaks. Rifampin, ceftriaxone, azithromycin,[13] and quinolones (but not penicillin) have the ability to eradicate meningococci in the nasopharynx. Most meningococcal isolates are now resistant to sulfonamides; resistance to rifampin can develop rapidly, and quinolone-resistant meningococci are increasing.

Providing vaccination to at-risk individuals is the best option for the long-term control of meningococcal disease.[14] Meningococcal polysaccharide-protein conjugate vaccines for A, C, Y, and W have been used globally and can decrease nasopharyngeal carriage of meningococci as well as invasive meningococcal disease.[15] Vaccination is recommended for children ages 2

TABLE 274-2 CHEMOPROPHYLAXIS AGAINST MENINGOCOCCAL INFECTION

DRUG	AGE GROUP	DOSAGE	DURATION AND ROUTE OF ADMINISTRATION*	CONSIDERATIONS
Rifampin	Children <1 month	5 mg/kg q12h	2 days, oral	
	Children >1 month	10 mg/kg q12h (maximum, 600 mg)	2 days, oral	Rifampin can interfere with efficacy of oral contraceptives and some seizure prevention and anticoagulant medications; may stain soft contact lenses
	Adults	600 mg q12h	2 days, oral	Not recommended for pregnant women
Ceftriaxone	Children <15 years	125 mg	Single IM dose	
	Children >15 years and adults	250 mg	Single IM dose	Ceftriaxone is recommended for prophylaxis in pregnant women
Ciprofloxacin	Adults	500 mg	Single dose, oral	Not recommended routinely for persons <18 years of age, but use in infants and children (20 mg/kg) may be justified after careful assessment of the risks and benefits Not recommended for pregnant or lactating women Cases of ciprofloxacin resistance have been increasingly reported and use for prophylaxis should be based on local sensitivity of the meningococcus to the drug
Azithromycin		10 mg/kg (maximum, 500 mg)	Single dose, oral	Equivalent to rifampin for eradication of meningococci from nasopharynx, but data are limited

ANTIBIOTIC CHEMOPROPHYLAXIS FOR HOUSEHOLD OR INTIMATE CONTACTS

- Household contacts and persons sharing the same living quarters, particularly young children
- Daycare center, nursery school, or child-care contacts; frequent playmates of young children
- Close social contacts who were exposed to oral secretions in the week before onset, such as by kissing and sharing of eating and drinking utensils or toothbrushes
- For airline travel lasting more than 8 hours, passengers who are seated directly next to an infected person should receive prophylaxis.
- Routine prophylaxis is not recommended for health care professionals unless they have had intimate exposure to respiratory secretions.
- Because the risk for secondary cases is highest during the first few days after exposure, chemoprophylaxis should be initiated as soon as possible, ideally <24 hours after identification of the index patient.
- If more than 14 days have passed since the last contact with the index patient, chemoprophylaxis is not likely to be of benefit.
- Pharyngeal cultures are not helpful in determining the need for chemoprophylaxis and may unnecessarily delay the use of effective chemoprophylaxis.
- Chemoprophylaxis has also been recommended for patients given penicillin or chloramphenicol for treatment because pharyngeal carriage may not be eliminated with these antibiotics and the patient could remain colonized with a virulent strain.
- Ceftriaxone is recommended for pregnant women.
- May want to avoid ciprofloxacin or azithromycin in individuals at risk for QT-prolongation.

*Administered orally unless otherwise stated.
Recommended groups for chemoprophylaxis based on exposure to the case in the week before onset of illness.
IV = intravenous.

months to 10 years who are at increased risk for meningococcal disease and then routinely in older children and adolescents (first dose at the age of 11 or 12 years with booster at 16 years). Populations that especially benefit from new conjugate vaccines are college freshmen, military recruits, patients with immunoglobulin or complement deficiencies (inherited or chronic deficiencies such as C3, properdin, factor D, or late complement components), patients with anatomic or functional asplenia, laboratory workers who are routinely exposed to isolates of *N. meningitidis*, adults with HIV infection, and people who travel to or reside in countries where *N. meningitidis* is epidemic.

A meningococcal conjugate vaccine for Africa (MenAfriVac) costs less than $0.50 a dose and is used as a mass vaccination strategy for individuals 1 to 29 years old. By the end of 2020, more than 315 million doses were administered and over 150,000 lives saved. This program has resulted in the virtual elimination of group A meningococcal disease in the 24 meningitis belt countries vaccinated.

The development of vaccines for group B *N. meningitidis* has also shown significant progress.[A2] Two group B vaccines, MenB-4C (Bexsero) and MenB-FHbp (Trumenba), are now licensed based on their immunogenicity and safety.[16] For example, group B is the predominant cause of meningococcal disease in infants, and introduction of the group B vaccine (MenB-4C) into the publicly funded national immunization program of the United Kingdom had a 60% efficacy at 1 year.[17] These vaccines have been especially useful during localized outbreaks, such as on U.S. college campuses.[18,19] However, unlike the A, C, W, Y conjugate vaccines, group B vaccines have minimal effect on decreasing pharyngeal carriage of the organism and do not provide herd protection.[20]

Prevention of meningococcal disease in patients who are receiving C5 inhibitors (eculizumab or the long-acting derivative ravulizumab) is a special concern. Eculizumab, which is a humanized monoclonal antibody that binds C5 and inhibits the terminal complement pathway, is approved for use in complement-mediated thrombotic microangiopathies (such as paroxysmal nocturnal hemoglobinuria [Chapter 146]), atypical hemolytic uremic syndrome (Chapter 158), and myasthenia gravis (Chapter 390). The risk of meningococcal disease in individuals receiving eculizumab is increased 2000-fold. Both ACWY and Men B vaccines are recommended before individuals receive eculizumab, but vaccine-induced protection is incomplete, possibly because of eculizumab's inhibition of complement-mediated bactericidal activity and also inhibition of opsonic and phagocytic functions. Over 50% of meningococcal infections in patients who are receiving eculizumab are due to non-groupable strains. Antibiotic chemoprophylaxis is recommended, but resistant strains can develop. Education for enlightened awareness, early care, vaccination of close contacts, and administration of ceftriaxone or other effective antibiotic agents at first signs of symptoms (fever, headache, altered mental state, rash) are recommended.

PROGNOSIS

The mortality of untreated systemic meningococcal disease is 70 to 90%. Despite highly effective antibiotics and aggressive supportive care, the mortality of invasive meningococcal disease remains about 10%. The failure to recognize disease early, the very rapid development of disease (especially meningococcemia), and the delay in administering antibiotics remain the most significant challenges. The chance of surviving shock is directly correlated to plasma concentrations of endotoxin, and half of the nonsurviving patients with shock die within the first 12 hours of hospital admission.

Long-term sequelae and morbidity after invasive meningococcal disease are significant.[21] Neurologic impairment occurs in 7 to 10% with meningococcal meningitis, with palsies of the sixth, seventh, and eighth cranial nerves as well as hemiparesis and quadriparesis. Unilateral or bilateral sensorineural hearing loss occurs in 2 to 9% of cases, is profound in 2% of affected individuals, and necessitates cochlear implantation in 0.4%. Neurodevelopmental impairment, including behavioral and psychological problems, learning difficulties, memory deficits, executive function problems, decreased academic performance, spasticity, seizures, and focal neurologic signs, is seen in approximately 10%. Visual difficulties, seizures, and motor deficits are reported in 2 to 3%, with multiple

neurologic disabilities occurring in 1 to 2% of affected individuals. About 5 to 20% of survivors of meningococcal sepsis in childhood have long-term behavioral and emotional problems, decreased intellectual functioning, and illness-related physical or social consequences.

Scarring of the skin, secondary to necrotic purpura, may vary from unnoticeable to requiring skin grafting. Multiple areas may be involved; the lower limbs are most frequently affected, followed by the arms, chest, and face. Multiple amputations of the digits or limbs may be required owing to necrosis of the skin, muscle, and bone of the affected parts (see Fig. 274-2D). Bone growth disturbances, stump overgrowth, scar contractures, and soft tissue and bone infections may complicate amputations. Limb-length discrepancies, which may result from infarction of the growth plate, often necessitate further surgical intervention. Following acute renal failure at presentation, renal function recovers in most individuals; however, evidence of renal dysfunction may persist for more than 4 years in both children and adults, with the risk being higher in patients who required renal replacement therapy.

Meningococcal disease and its complications, often occurring rapidly in otherwise healthy individuals, also produce significant family, community, health care, and public health impact. The emotional toll on individuals who survive and on their families is considerable and a global phenomenon. In communities, meningococcal disease may also create fear and anxiety. In one study, post-traumatic stress disorder (Chapter 362) occurred in 15% of children, in half of the mothers, and in 20% of fathers at 3 months. Meningococcal disease and its complications also result in substantial hospital and long-term health care costs. Furthermore, delay in the diagnosis of meningococcal sepsis and meningitis and septicemia is a common reason for litigation.

If parents and health care professionals recognize the importance of fever and headache with or without a rash and seek treatment early, morbidity and mortality can be reduced with prehospital antibiotic treatment, rapid transportation to medical facilities, and stabilization in an intensive care unit. Prevention of meningococcal disease with new vaccines and vaccine strategies remains the major worldwide goal.

275 *NEISSERIA GONORRHOEAE* INFECTIONS

JEFFREY D. KLAUSNER AND STEPHANIE N. TAYLOR

DEFINITION

Neisseria gonorrhoeae, which is predominantly a sexually transmitted infection, is a common cause of urethral discharge in men and cervical discharge in women. Because *N. gonorrhoeae* may infect mucosal epithelial cells, it also may cause pharyngeal and rectal infection in adults and conjunctival infection in the newborn. Complications of *N. gonorrhoeae* infections include epididymitis in males and pelvic inflammatory disease in females. Chronic or recurrent pelvic inflammatory disease may result in uterine tubal scarring and subsequent infertility. Additional complications may include disseminated infection with resultant skin lesions, arthritis, tenosynovitis, and rarely, endocarditis or meningitis. Gonococcal infections also may increase the risk of acquiring and transmitting the human immunodeficiency virus (HIV) infection.

The Pathogen

N. gonorrhoeae are gram-negative bacteria typically observed microscopically as diplococci. The organism is composed of an inner cytoplasmic membrane, a middle cell wall composed of peptidoglycan, and an outer membrane. The outer membrane contains various components that interact with the host, thereby enabling invasion and infection, as well as mutant surface proteins and lipo-oligosaccharides that facilitate the evasion of host immunity. *N. gonorrhoeae* have a genome of circular DNA of 2.1 million base pairs. The genome contains 2069 genes, many of which are involved in DNA repair pathways.

EPIDEMIOLOGY

N. gonorrhoeae is a sexually transmissible organism. Very rarely it can be acquired through the inadvertent inoculation of infected secretions onto a susceptible anatomic site (e.g., causing gonococcal orbital cellulitis[1] or be associated with household transmission). Mother-to-child transmission from passage of the fetus through an infected birth canal can result in neonatal gonococcal conjunctivitis, which can lead to blindness if untreated.

The infectivity of gonorrhea is about 50%, which on its own would not allow the maintenance of endemic infection without core groups of individuals who have a higher than average number of sexual contacts. The likelihood that an infected man will transmit infection to a woman during a single episode of unprotected vaginal intercourse is about 50 to 70%, and the risk that a woman will infect a man is about 20%. The risks of transmission associated with fellatio and cunnilingus are not well defined. Anal intercourse is also an efficient mode of transmission, but the absolute risk of transmission per contact is uncertain. Evidence also suggests gonococcal transmission from the use of infected saliva as a sexual lubricant.

After changes in sexual behavior due to the wide availability of oral contraceptive agents and the rise of the gay liberation movement in the 1970s, cases of gonorrhea soared in the United States. The discovery of HIV and the resultant fear of AIDS in the 1980s led to changes in sexual behaviors that reduced the incidence of gonorrhea to an all-time low by the mid-1990s. Over the past two decades, cases of gonorrhea have increased again, primarily in men who have sex with men, but also in younger minority populations and in groups with poor access to health care. Infections now are most common among females ages 15 to 24 years and males ages 20 to 29 years. Currently, gonorrhea is the second most frequently reported disease in the United States, with an estimated 1.6 million new infections per year.[2]

Globally, *N. gonorrhoeae* is the most commonly notifiable infection after *Chlamydia trachomatis*, with an estimated annual incidence of 87 million new cases and a population-level prevalence of about 0.7 to 0.9%.[3] In pregnant women in sub-Saharan Africa, *N. gonorrhoeae* has a prevalence of 2.3% overall, with higher frequencies in Southern versus Central Africa. Antimicrobial-resistant *N. gonorrhoeae* infections are widespread and increasing.[4]

PATHOBIOLOGY

N. gonorrhoeae contain a variety of virulence and growth factors. Their characteristic filamentous structures, called pili, serve to attach to membranes of human mucosal and uroepithelial cells. Variations in pili contribute to immune evasion and tissue tropism. *N. gonorrhoeae* also have porins, which are proteins on the outer membrane, that enable the transport of ions and nutrients essential for bacterial survival. Certain porins, such as porin B isoform 1A, have been associated with increased resistance to host immunity and an increased capacity for dissemination. Opacity-associated proteins are integral outer membrane proteins that determine the invasive capacity of *N. gonorrhoeae*. Gonococci may also evade host immunity by expressing enzymes such as IgA proteases, which cleave mucosal antibody and use several molecular mechanisms to vary surface antigens such as lipo-oligosaccharides.

Select complement deficiencies (Chapter 37) predispose a patient to dissemination of *N. gonorrhoeae* because of decreased complement-mediated killing of *N. gonorrhoeae*. Up to 50% of patients with C6, C7, or C8 complement deficiencies may develop bacteremia with pathogenic *Neisseria* species. Complement deficiencies also predispose patients to recurrent and perhaps subacute or even chronic infections. Eculizumab, a monoclonal antibody to C5 used in conditions such as complement-mediated hemolytic uremic syndrome (Chapter 158), also appears to increase the risk of disseminated gonococcal infection.[5]

CLINICAL MANIFESTATIONS

The clinical manifestations of gonorrhea are highly dependent on the anatomic site of infection and host factors related to inflammation. *N. gonorrhoeae* may infect the mucosal tissue of the urethra, cervix, throat, or rectum. Infections at

neurologic disabilities occurring in 1 to 2% of affected individuals. About 5 to 20% of survivors of meningococcal sepsis in childhood have long-term behavioral and emotional problems, decreased intellectual functioning, and illness-related physical or social consequences.

Scarring of the skin, secondary to necrotic purpura, may vary from unnoticeable to requiring skin grafting. Multiple areas may be involved; the lower limbs are most frequently affected, followed by the arms, chest, and face. Multiple amputations of the digits or limbs may be required owing to necrosis of the skin, muscle, and bone of the affected parts (see Fig. 274-2D). Bone growth disturbances, stump overgrowth, scar contractures, and soft tissue and bone infections may complicate amputations. Limb-length discrepancies, which may result from infarction of the growth plate, often necessitate further surgical intervention. Following acute renal failure at presentation, renal function recovers in most individuals; however, evidence of renal dysfunction may persist for more than 4 years in both children and adults, with the risk being higher in patients who required renal replacement therapy.

Meningococcal disease and its complications, often occurring rapidly in otherwise healthy individuals, also produce significant family, community, health care, and public health impact. The emotional toll on individuals who survive and on their families is considerable and a global phenomenon. In communities, meningococcal disease may also create fear and anxiety. In one study, post-traumatic stress disorder (Chapter 362) occurred in 15% of children, in half of the mothers, and in 20% of fathers at 3 months. Meningococcal disease and its complications also result in substantial hospital and long-term health care costs. Furthermore, delay in the diagnosis of meningococcal sepsis and meningitis and septicemia is a common reason for litigation.

If parents and health care professionals recognize the importance of fever and headache with or without a rash and seek treatment early, morbidity and mortality can be reduced with prehospital antibiotic treatment, rapid transportation to medical facilities, and stabilization in an intensive care unit. Prevention of meningococcal disease with new vaccines and vaccine strategies remains the major worldwide goal.

275 *NEISSERIA GONORRHOEAE* INFECTIONS

JEFFREY D. KLAUSNER AND STEPHANIE N. TAYLOR

DEFINITION

Neisseria gonorrhoeae, which is predominantly a sexually transmitted infection, is a common cause of urethral discharge in men and cervical discharge in women. Because *N. gonorrhoeae* may infect mucosal epithelial cells, it also may cause pharyngeal and rectal infection in adults and conjunctival infection in the newborn. Complications of *N. gonorrhoeae* infections include epididymitis in males and pelvic inflammatory disease in females. Chronic or recurrent pelvic inflammatory disease may result in uterine tubal scarring and subsequent infertility. Additional complications may include disseminated infection with resultant skin lesions, arthritis, tenosynovitis, and rarely, endocarditis or meningitis. Gonococcal infections also may increase the risk of acquiring and transmitting the human immunodeficiency virus (HIV) infection.

The Pathogen

N. gonorrhoeae are gram-negative bacteria typically observed microscopically as diplococci. The organism is composed of an inner cytoplasmic membrane, a middle cell wall composed of peptidoglycan, and an outer membrane. The outer membrane contains various components that interact with the host, thereby enabling invasion and infection, as well as mutant surface proteins and lipo-oligosaccharides that facilitate the evasion of host immunity. *N. gonorrhoeae* have a genome of circular DNA of 2.1 million base pairs. The genome contains 2069 genes, many of which are involved in DNA repair pathways.

EPIDEMIOLOGY

N. gonorrhoeae is a sexually transmissible organism. Very rarely it can be acquired through the inadvertent inoculation of infected secretions onto a susceptible anatomic site (e.g., causing gonococcal orbital cellulitis[1] or be associated with household transmission). Mother-to-child transmission from passage of the fetus through an infected birth canal can result in neonatal gonococcal conjunctivitis, which can lead to blindness if untreated.

The infectivity of gonorrhea is about 50%, which on its own would not allow the maintenance of endemic infection without core groups of individuals who have a higher than average number of sexual contacts. The likelihood that an infected man will transmit infection to a woman during a single episode of unprotected vaginal intercourse is about 50 to 70%, and the risk that a woman will infect a man is about 20%. The risks of transmission associated with fellatio and cunnilingus are not well defined. Anal intercourse is also an efficient mode of transmission, but the absolute risk of transmission per contact is uncertain. Evidence also suggests gonococcal transmission from the use of infected saliva as a sexual lubricant.

After changes in sexual behavior due to the wide availability of oral contraceptive agents and the rise of the gay liberation movement in the 1970s, cases of gonorrhea soared in the United States. The discovery of HIV and the resultant fear of AIDS in the 1980s led to changes in sexual behaviors that reduced the incidence of gonorrhea to an all-time low by the mid-1990s. Over the past two decades, cases of gonorrhea have increased again, primarily in men who have sex with men, but also in younger minority populations and in groups with poor access to health care. Infections now are most common among females ages 15 to 24 years and males ages 20 to 29 years. Currently, gonorrhea is the second most frequently reported disease in the United States, with an estimated 1.6 million new infections per year.[2]

Globally, *N. gonorrhoeae* is the most commonly notifiable infection after *Chlamydia trachomatis*, with an estimated annual incidence of 87 million new cases and a population-level prevalence of about 0.7 to 0.9%.[3] In pregnant women in sub-Saharan Africa, *N. gonorrhoeae* has a prevalence of 2.3% overall, with higher frequencies in Southern versus Central Africa. Antimicrobial-resistant *N. gonorrhoeae* infections are widespread and increasing.[4]

PATHOBIOLOGY

N. gonorrhoeae contain a variety of virulence and growth factors. Their characteristic filamentous structures, called pili, serve to attach to membranes of human mucosal and uroepithelial cells. Variations in pili contribute to immune evasion and tissue tropism. *N. gonorrhoeae* also have porins, which are proteins on the outer membrane, that enable the transport of ions and nutrients essential for bacterial survival. Certain porins, such as porin B isoform 1A, have been associated with increased resistance to host immunity and an increased capacity for dissemination. Opacity-associated proteins are integral outer membrane proteins that determine the invasive capacity of *N. gonorrhoeae*. Gonococci may also evade host immunity by expressing enzymes such as IgA proteases, which cleave mucosal antibody and use several molecular mechanisms to vary surface antigens such as lipo-oligosaccharides.

Select complement deficiencies (Chapter 37) predispose a patient to dissemination of *N. gonorrhoeae* because of decreased complement-mediated killing of *N. gonorrhoeae*. Up to 50% of patients with C6, C7, or C8 complement deficiencies may develop bacteremia with pathogenic *Neisseria* species. Complement deficiencies also predispose patients to recurrent and perhaps subacute or even chronic infections. Eculizumab, a monoclonal antibody to C5 used in conditions such as complement-mediated hemolytic uremic syndrome (Chapter 158), also appears to increase the risk of disseminated gonococcal infection.[5]

CLINICAL MANIFESTATIONS

The clinical manifestations of gonorrhea are highly dependent on the anatomic site of infection and host factors related to inflammation. *N. gonorrhoeae* may infect the mucosal tissue of the urethra, cervix, throat, or rectum. Infections at

ABSTRACT

Neisseria gonorrhoeae, which is a predominantly sexually transmitted infection, is a common cause of urethral discharge in men and cervical discharge in women. Because *N. gonorrhoeae* may infect mucosal epithelial cells, it also may cause pharyngeal and rectal infection in adults and conjunctival infection in the newborn. Infection may or may not be symptomatic depending on the anatomic site of infection and characteristics of the host and organism.

Complications of *N. gonorrhoeae* infections include epididymitis in males and pelvic inflammatory disease in females. Chronic or recurrent pelvic inflammatory disease may result in uterine tubal scarring and subsequent infertility. Additional complications may include disseminated infection with resultant skin lesions, arthritis, tenosynovitis, and rarely, endocarditis or meningitis. Gonococcal infections may increase the risk of acquiring and transmitting the human immunodeficiency virus infection. Diagnosis is confirmed by nucleic acid testing, Gram stain, or culture.

Timely treatment with effective antibacterial therapy is highly curative, but antimicrobial-resistant infections are increasing. Gonococcal infections may be prevented with the consistent use of condoms for sexual intercourse. Routine screening of sexually active or pregnant women under the age of 25 years and of men who have sex with men is an additional strategy to prevent the complications and spread of gonococcal infections. Epidemiologic research suggests that certain meningococcal vaccines might reduce the acquisition of *N. gonorrhoeae*.

these sites may produce an inflammatory response with subsequent purulent discharge or pain (often burning in character) with urination or defecation, or, as is often the case in pharyngeal infection, either mild symptoms (e.g., sore throat) or no symptoms whatsoever. After a brief incubation period, typically just 1 or 2 days, acute genital infections are almost always (>90%) symptomatic in men but much less so (about 50%) in women, a difference that partly explains why asymptomatically infected women contribute to ongoing transmission.

Clinical manifestations in women may include pain with intercourse, vaginal bleeding, and lower abdominal pain and tenderness with or without fever, consistent with pelvic inflammatory disease (Chapter 264). Repeated pelvic inflammatory disease increases the risk for tubal infertility. Infection in pregnancy can lead to adverse birth outcomes including prematurity, low birthweight, and neonatal mortality.[6] In HIV-infected pregnant women, gonococcal coinfection can increase the mother-to-child transmission of HIV infection. In men, prolonged infection may lead to testicular infection and epididymitis.

Rarely, when infection does not cause acute symptoms that lead to diagnosis and effective therapy, *N. gonorrhoeae* may disseminate in the blood stream and seed normally sterile sites, including the joints, cerebrospinal fluid, and heart valves. Disseminated gonococcal infection may also be associated with a pustular skin rash and inflammation of the affected joints and tendons.

DIAGNOSIS

Diagnosis is based on recent sexual exposure, clinical signs, and symptoms. Laboratory confirmation of infection is made by the use of nucleic acid–based molecular testing (of a swab from the urethra, cervix, vagina, throat, or rectum; or of urine),[7] antigen-based immunoassays, or the observation of characteristic organisms with the distinct morphology and coloration on point-of-care Gram staining. After heat-fixing the urethral smear slide, the multistep Gram stain procedure allows visualization of the nearly pathognomonic gram-negative intracellular diplococci upon oil-immersion microscopy (Fig. 275-1A). A methylene blue/gentian violet stain (Fig. 275-1B), which does not require heat fixation and takes only 1 minute, is an equally good alternative. Because *N. gonorrhoeae* are typically restricted to specific anatomic sites of infection, testing for infection must occur with specimens from each anatomic site of sexual exposure. Urine tests detect urethral infections but not infections at other anatomic sites. Culture is rarely required except in cases of possible treatment failure or to diagnose disseminated gonococcal infection, abscesses, endocarditis, or meningitis. Rarely, other *Neisseria* species (e.g., *Neisseria meningitides*; Chapter 276) may also be present in urethral secretions and may be associated with a similar syndrome.

SPECIFIC CLINICAL SYNDROMES

Localized Infections

URETHRITIS

CLINICAL MANIFESTATIONS

Urethritis is the most common clinical manifestation of gonococcal infection in men. After an incubation period of 2 to 6 days, men develop a profuse, purulent urethral discharge that is usually white, yellow, or green in color (Fig. 275-2A). In contrast, the discharge in non-gonococcal urethritis is usually thin and clear or gray in color (Fig. 275-2B). Dysuria is common; meatal irritation, meatal erythema, and penile lymphedema can also occur. Depending on the infecting strain, 10% of men have an asymptomatic infection that is only detected by screening. Because the diplococci of *N. gonorrhoeae* adhere to mucosal columnar and cuboidal epithelial cells of the urethra and cervix, women can also have symptomatic urethritis with dysuria.

DIAGNOSIS

The diagnosis of gonococcal urethritis should be suspected based on dysuria with a urethral discharge (i.e., burning with urination). Gonococcal urethritis

may be confirmed with point-of-care Gram stain, methylene blue stain, or nucleic acid detection testing of the urethral discharge by a penile meatal or urethral swab. In women, nucleic acid testing of urine or self-collected vaginal swab specimens has replaced the need to collect cervical swab specimens.

CERVICITIS

CLINICAL MANIFESTATIONS

Cervicitis is the most common clinical manifestation of gonococcal infection in women, but up to 50% of infections are asymptomatic. When symptomatic, women report vaginal discharge, irritation, or itching. Postcoital bleeding, pain with vaginal sexual intercourse, and abnormal vaginal bleeding are also associated with cervicitis. The physical examination may show a purulent or mucopurulent cervical discharge (Fig. 275-3), an erythematous or edematous cervix, a friable cervix with easily induced bleeding, or, occasionally, cervical motion tenderness.

DIAGNOSIS

Nucleic acid amplification testing is the mainstay for detecting urogenital *N. gonorrhoeae* from the cervix, vagina, and urine in women because other methods are not sufficiently sensitive for detecting the organism. Other organisms that may be detected by nucleic acid testing (Chapter 264) include *Chlamydia trachomatis* (Chapter 294), *Mycoplasma genitalium* (Chapter 293), *Trichomonas vaginalis* (Chapter 324), herpes simplex viruses (Chapter 345), and *Candida* species (Chapter 310), but no etiology is found in 50% of women with cervicitis.

PROCTITIS

CLINICAL MANIFESTATIONS

Rectal gonorrhea most commonly occurs in men who have sex with men and in women. In men who have sex with men, the exposure to the organism is almost always via receptive anal intercourse. In women, the usual source of rectal *N. gonorrhoeae* is vaginal and cervical secretions that contaminate the rectum, but women who engage in receptive anal intercourse may acquire the organism by direct sexual activity as well. Heterosexual men can also acquire rectal gonorrhea from digital-anal inoculation, but rates are much lower compared with men who have sex with men and women.

Most infections are asymptomatic, but symptoms are more common in men who have sex with men due to more frequent anal intercourse and concurrent trauma, as well as the size of the inoculum. Typical symptoms are anal irritation and pruritus, rectal discharge, and mucus-coated stools. Tenesmus and pain or bleeding may occur with bowel movements.

DIAGNOSIS

Because most cases of rectal gonorrhea are asymptomatic, many cases are missed due to lack of anorectal screening. Infection is detected with nucleic acid amplification testing, often combined with testing for *Chlamydia trachomatis* (Chapter 294). A self-collected nucleic acid specimen is as accurate as specimen collection performed by a clinician.[8] In many cases, the rectum is the only site that will test positive. Rectal gonorrhea increases the risk of HIV acquisition in persons who engage in receptive anal intercourse, so such individuals should be screened for asymptomatic rectal *N. gonorrhoeae*.

Other causes of proctitis include *Chlamydia trachomatis*, herpes simplex viruses (Chapter 345), syphilis (Chapter 295), Crohn disease (Chapter 127), lymphogranuloma venereum (Chapter 294), anal fissures (Chapter 131), and other enteric microbes (Chapter 262).

PHARYNGITIS

CLINICAL MANIFESTATIONS

Over 90% of pharyngeal gonorrhea is asymptomatic. When signs and symptoms are present, they are identical to those of pharyngitis caused by other organisms (Chapter 397), especially group A streptococcus (Chapter 269). Typical clinical findings include pharyngeal erythema and edema, tonsillitis, fever, tonsillar exudates, and cervical lymphadenopathy.

DIAGNOSIS

Pharyngeal gonorrhea is confirmed with nucleic acid amplification testing. Similar to rectal gonorrhea, self-collection of a clinical specimen is an accurate alternative to a clinician-collected specimen. If positive, throat culture can aid in testing for antimicrobial susceptibility.

GONORRHEA IN PREGNANCY

Pregnancy is a risk factor for gonorrhea, and routine screening is an important preventive measure.[9] Complications of gonorrheal infection in pregnant women include miscarriage, premature delivery, premature rupture of membranes, and chorioamnionitis. A serious clinical complication is when the infection is transmitted to the newborn during delivery and causes ophthalmia neonatorum, which is a conjunctivitis that can cause corneal damage and lead to blindness. Rarely, septic arthritis or disseminated gonococcal infection may occur in the newborn.

TREATMENT

The current U.S. recommendation for the treatment of uncomplicated gonorrhea of the urethra, cervix, rectum, or throat is a single dose of ceftriaxone 500 mg by intramuscular injection.[10,11] If chlamydia is also a possibility, doxycycline (100 mg orally twice daily for 7 days) should be added (see Table 264-5); if adherence is an issue, 1 g oral azithromycin given once can substitute for doxycycline. European guidelines recommend ceftriaxone (1 g intramuscularly) plus azithromycin (2 g orally once).[12] An alternative to ceftriaxone is cefixime (800 mg one dose orally).[A1] When a molecular gyrase A test is available and predicts ciprofloxacin susceptibility, ciprofloxacin (500 mg one dose orally) may be used.[13]

If patients are allergic to cephalosporins or have a resistant organism, single-dose gentamicin (240 mg intramuscularly) plus azithromycin (2 g orally) is recommended.[A2] Gentamicin monotherapy is unreliable for pharyngeal gonorrhea, but azithromycin (2 g orally) appears to be effective.

Patients treated for pharyngeal infection should undergo a test of cure at 7 to 14 days after treatment. Pregnant women treated for gonorrhea should undergo a test of cure by repeat nucleic acid amplification testing at 3 to 4 weeks after treatment. Because of the high incidence of repeated infection, all treated patients should undergo screening at 3 months after treatment to exclude a new infection.

Treatment of Partners

Effective partner treatment, which is a mainstay of gonococcal therapy and the public health efforts to control the spread of infection, can significantly reduce the rate of repeat infection. The medical standard of care for the management of gonorrhea requires that any index patient's sex partner within the past 60 days receive treatment through a medical visit or expedited-partner therapy. Expedited-partner therapy[14,15] provides patients with either medication (e.g., a single 800-mg oral dose of cefixime) to give to their partner or partners, a prescription for the additional treatment, or an order directly with the partner's pharmacy.

PROGNOSIS

Urethritis

The overall prognosis of gonococcal urethritis is very good with appropriate treatment. Occasionally, however, urethritis can be complicated by epididymitis, penile cellulitis, periurethral abscess, penile edema, and prostatitis. Epididymitis is usually unilateral. Pain and swelling are localized to the epididymis. Treatment of epididymitis should cover both gonococci and *Chlamydia trachomatis* with a 500-mg intramuscular dose of ceftriaxone plus doxycycline (100 mg orally twice daily for 10 days). In men who have insertive anal intercourse, levofloxacin (500 mg orally daily for 10 days) should be used instead of doxycycline to cover enteric organisms and *Chlamydia trachomatis*. Acute pain in the testicle or other areas of the scrotum warrants immediate evaluation to exclude testicular torsion or abscess. Penile cellulitis, edema, and abscess usually respond to standard single-dose gonococcal treatment, and surgical intervention is not necessary.

Cervicitis

The overall prognosis of gonococcal cervicitis is very good with appropriate treatment. The most serious complication of gonococcal cervicitis is progression to upper genital tract infection or pelvic inflammatory disease (see later). Other complications include Bartholin gland abscess and infection of the Skene glands, which are located in the periurethral area. Bartholin gland abscesses may require incision and drainage. Skenitis is treated conservatively with oral antibiotics and local measures such as warm compresses. Surgical intervention is rarely needed, but may be warranted if it persists despite antibiotic therapy.

Rectal Infection

Untreated rectal gonorrhea usually resolves at a median of 2 to 3 months, but can persist for 6 to 11 months.[16] With treatment, it typically resolves within a week. Occasionally, fecal impaction and constipation may occur due to severe pain with bowel movements. Liquid stool leakage around the impaction can be confused with bowel incontinence. Complications can include anal hemorrhoids, anal tears, bleeding (Chapter 131), and rarely, tears in the colonic wall. Complications can be avoided or moderated by conservative measures, such as the use of laxatives.

Pharyngeal Infection

Even without treatment, most infections clear spontaneously within 4 months.[17] However, pharyngeal gonorrhea may place individuals at risk for disseminated infection, and gonococcal pharyngeal infection likely contributes to the community spread of infection.

PELVIC INFLAMMATORY DISEASE

CLINICAL MANIFESTATIONS

Pelvic inflammatory disease (PID; Chapter 264) is an upper genital tract syndrome that includes one or more of the following: salpingitis, endometritis, oophoritis, or peritonitis. An estimated 10 to 40% of women with untreated lower tract gonococcal infection progress to develop pelvic inflammatory disease. Women with pelvic inflammatory disease may report lower abdominal pain, nausea, vomiting, fever, chills, vaginal discharge, or abnormal vaginal bleeding. Diffuse abdominal pain or right upper quadrant pain from gonococcal peritonitis or perihepatitis (Fitz-Hugh-Curtis syndrome) can mimic cholecystitis or hepatitis. Pelvic and bimanual examination findings include cervical motion tenderness, pelvic pain, uterine fundal tenderness, diffuse abdominal pain, bilateral or unilateral adnexal pain, and cervical discharge.

DIAGNOSIS

The diagnosis is often based on clinical criteria,[18,19] which include lower abdominal pain, adnexal tenderness, cervicitis, cervical motion tenderness, and leukocytes in the vaginal discharge. Nucleic acid amplification testing can help establish an etiologic diagnosis (Chapter 264). If pelvic inflammatory disease is suspected, pelvic or transvaginal ultrasound should be the initial test. Ultrasound findings include tubal hyperemia, thickened and fluid-filled uterine tubes, free-flowing or localized fluid collections with or without complex phlegmon, or frank abscess.

Ultrasound can guide immediate drainage of an ovarian or pelvic abscess. If needed, magnetic resonance imaging (MRI) of the pelvis can better define areas of question on the ultrasound. Abdominal computerized tomographic scanning is recommended to evaluate for complications that extend beyond the pelvis, such as generalized peritonitis or perihepatitis. Laparoscopy, which is rarely used as the initial diagnostic method, typically shows edema and erythema of the tubal surface, sometimes with thick exudate on the tubal surface or exuding from the uterine tubes.

Women with *N. gonorrhoeae* may have simultaneous infection with *Chlamydia trachomatis* and with other vaginal organisms, including anaerobic bacteria as well as gram-negative and gram-positive cocci, rods, and coccobacilli. Special attention must be given to lower quadrant pain and adnexal pain to ensure that the patient does not have acute appendicitis (Chapter 128), ectopic pregnancy (Chapter 218), rupture or torsion of an ovarian cyst, a tubo-ovarian abscess, renal or ureteral stones (Chapter 111), urinary tract infection (Chapter 263), inflammatory bowel disease (Chapter 127), or another acute abdominal condition (Chapter 128).

TREATMENT

For pelvic inflammatory disease (Chapter 264), treatment may be oral or parenteral (Table 264-5), depending on how sick the patient is. Most women can be treated as outpatients, but inpatient treatment is recommended for women who are pregnant; may have other diagnoses that may require emergency surgery, such as appendicitis, or ectopic pregnancy; have significant nausea and vomiting that may preclude the use of oral medications; have disseminated gonorrhea, peritonitis, or perihepatitis; have any evidence of systemic sepsis, or have a tubo-ovarian abscess. Treatment should routinely cover gonococcal and chlamydial species (Table 264-5), as well as anaerobic organisms.[A3]

PROGNOSIS

Even with successful treatment, pelvic inflammatory disease can cause tubal scarring and tubal obstruction. After one episode of pelvic inflammatory disease, almost 10% of women may develop tubal occlusion and infertility. After two episodes, the risk is 20%, and after three or more episodes, it is 40%.[20] Even without subsequent tubal occlusion, the risk of future ectopic pregnancy is markedly increased in women with a history of pelvic inflammatory disease. Many women also have residual chronic pelvic pain.

DISSEMINATED GONOCOCCAL INFECTION

CLINICAL MANIFESTATIONS

N. gonorrhoeae bacteremia with disseminated gonococcal infection complicates less than 1% of cases. Manifestations can range from mild joint discomfort and several skin lesions to sepsis with asymmetric polyarthritis, numerous skin lesions, and prostration. Dissemination is substantially more common in women because the initial local infection is less likely to cause symptoms that lead to early treatment. In women, dissemination is often associated with menstruation or pregnancy. At the time of bacteremia, most individuals have no symptoms at mucosal sites because the strains of *N. gonorrhoeae* that are prone to disseminate are unlikely to cause local mucosal inflammation.

The two distinct presentations of disseminated gonococcal infection are tenosynovitis/dermatitis, which is seen in about 70% of cases, and metastatic infection. Tenosynovitis/dermatitis begins with tenosynovitis and migratory arthralgias of the knees, elbows, or ankles. Skin lesions are usually fewer than 30 in number, typically are seen on the extremities, are classically described as pustules on an erythematous base, and can be petechial, papular, or nodular (Fig. 275-4). Though not always a well-defined progression from tenosynovitis-dermatitis, septic arthritis of one or two joints occurs after several days in untreated patients. Tenosynovitis can progress to septic monoarticular or oligoarticular arthritis, but septic arthritis is the initial presentation in about 30% of cases. Disseminated gonococcal infection usually spares the axial skeleton—a feature that helps distinguish it from reactive arthritis.

Disseminated gonococcal infection may be complicated by endocarditis, meningitis, or osteomyelitis. Gonococcal endocarditis occurs in 1 to 2% of patients with disseminated gonococcal infection, most often involving the aortic valve. Gonococcal endocarditis (Chapter 61) can lead to rapid valvular destruction and heart failure. Gonococcal meningitis is clinically indistinguishable from meningitis secondary to *Neisseria meningitidis* or any acute bacterial meningitis.

FIGURE 275-4. Disseminated gonococcal infection. Pustules on an erythematous base.

DIAGNOSIS

Disseminated gonococcal infection should be the initial consideration in any young, sexually active person with the acute onset of arthritis. Nucleic acid amplification testing of skin lesions and cultures of synovial fluid can establish the diagnosis. Blood cultures should also be obtained. About 20% of cases of tenosynovitis/dermatitis syndrome are proven based on a compatible clinical presentation with identification of gonococci on testing of blood, synovial fluid, or skin. About 80% of cases are classified as probable based on finding gonococci in a mucosal site specimen (but not from blood or another sterile site) or documenting that a sex partner has gonococcal infection. A possible case of disseminated gonococcal infection has the compatible clinical presentation but no positive diagnostic tests from blood or any other sites tested. Disseminated gonococcal infections must be distinguished from other causes of fever and rash (Chapter 259), as well as other monoarticular or usually asymmetrical oligoarthritis (Chapter 236), including other types of septic arthritis (Chapter 251), as well as reactive arthritis, which can be triggered by sexually acquired chlamydial infection (Chapter 254) but, unlike gonococcal arthritis, frequently involves the axial skeleton.

TREATMENT

Treatment for gonococcal-related arthritis and arthritis-dermatitis syndrome is ceftriaxone (1 g IM or IV every 24 hours), with added doxycycline (100 mg orally twice daily for 7 days) if chlamydial infection cannot be excluded. The intravenous component should also be continued for a minimum of 7 days or until the patient is afebrile (whichever is longer) after which the patient may complete the 7-day course with an oral regimen (e.g., cefixime 400 mg orally twice daily).

For gonococcal meningitis and endocarditis, the recommended regimen is ceftriaxone (1 to 2 g IV every 24 hours) plus doxycycline (100 mg orally twice daily for 7 days) if chlamydial infection has not been excluded. The intravenous component should also be continued for a minimum of 7 days or until the patient is afebrile (whichever is longer). Alternatives to ceftriaxone are cefotaxime (1 g IV every 8 hours) or ceftizoxime (1 g IV every 8 hours). Intravenous treatment should be for 10 to 14 days for meningitis and 4 or more weeks for endocarditis and osteomyelitis.

Gonococcal septic arthritis infections require drainage (Chapter 251), similar to staphylococcal arthritis. About 50% of cases of gonococcal endocarditis require valve replacement.

PROGNOSIS

Many cases clear spontaneously. Most patients with the tenosynovitis/dermatitis syndrome resolve their symptoms spontaneously or quickly with antibiotics, but some cases progress to septic arthritis. For gonococcal endocarditis and meningitis, mortality can be as high as 20%.

PREVENTION

The sexual transmission of *N. gonorrhoeae* can be greatly reduced by changes in sexual practices, including the use of condoms during oral, anal, or vaginal intercourse. Complications may also be reduced by screening to detect infectious individuals. In high-income settings, the routine screening of pregnant women and the preventive application of ocular antibacterial ointment at birth has essentially eliminated ophthalmic neonatorum, but it remains a problem in some resource-limited countries.

Screening

Based on substantial evidence,[A4] the United States Preventive Services Task Force recommends annual screening for gonorrhea to prevent complications such as pelvic inflammatory disease in all sexually active females younger than age 25 years and in females with increased risk for infection ages 25 years and older.[21] The U.S. Centers for Disease Control and Prevention (CDC) recommends screening men who have sex with men at least annually (and every 3 to 6 months if at increased risk) at all anatomic sites of exposure. Routine screening is not routinely recommended for males who are exclusively heterosexual and do not live in correctional settings.

Barrier Methods

Male and female condoms are highly effective barriers that reduce the likelihood of exposure and transmission. For condoms to be effective at reducing the transmission of gonorrhea, they must be used correctly and consistently. Clinicians should assure that both male and female patients understand the different types of condoms and how to use them correctly. Persons who practice using condoms and carry condoms with them are more likely to use them. Female condoms offer a female-controlled way to prevent gonorrhea and reduce a female's dependency on a male partner. Female condoms may also be safely used for receptive anal sex by both males and females.

Behavioral Intervention

Factors that put persons at increased risk for sexually transmissible infections include alcohol and substance use disorders, poverty, stigma, and governmental and institutional policies that discriminate based on gender, race, ethnicity, sexual orientation, and gender identity. Successful interventions to reduce individual risk must occur at the individual, community, and policy level. Individual-level behavioral counseling can reduce the risk for sexually transmitted infections.[22]

Microbial Prophylaxis and Vaccination

Antimicrobial pre-exposure or post-exposure prophylaxis may be partially efficacious against *N. gonorrhoeae* in sexually active adults. Furthermore, antiseptic mouthwash is not effective for preventing oropharyngeal infection.[A5] Epidemiologic data suggest that outer-membrane-vesical–containing meningococcal type B vaccines can reduce the rate of acquisition of gonorrhea by 30 to 40%.[23]

276 CHANCROID

STANLEY M. SPINOLA

DEFINITION

Chancroid is a sexually transmitted disease that is characterized by painful genital ulcers and inguinal lymphadenitis caused by *Haemophilus ducreyi*. *H. ducreyi* also is a major cause of nonsexually transmitted cutaneous ulcers in children who live in regions of the South Pacific and Africa where yaws (Chapter 295), which is a nonsyphilitic treponematosis that causes a disfiguring and debilitating childhood infectious disease, is endemic.

H. ducreyi is a gram-negative coccobacillus that is not a true *Haemophilus* species. Within the Pasteurellaceae, *H. ducreyi* is grouped in a distinct lineage with *Mannheimia haemolytica* and *Aggregatibacter* (formerly *Actinobacillus*) *pleuropneumoniae*. *H. ducreyi* is likely to have diverged from these animal respiratory pathogens to occupy its niche in the human epithelium.

EPIDEMIOLOGY

Chancroid, which is endemic in resource-poor regions of Africa and Asia, facilitates the transmission of human immunodeficiency virus (HIV-1). In the 1990s, the World Health Organization estimated the annual global prevalence of chancroid to be 4 to 6 million cases. Because of the widespread use of syndromic management, which consists of treatment for syphilis and chancroid without diagnostic testing, the prevalence of chancroid has dramatically declined in endemic areas. Chancroid can be maintained only in networks with high rates of multiple sex partners. Infected female sex workers play an important role in its epidemiology, and targeted treatment of sex workers can eradicate the disease in endemic areas. Despite these successes, chancroid persists in many

DIAGNOSIS

Disseminated gonococcal infection should be the initial consideration in any young, sexually active person with the acute onset of arthritis. Nucleic acid amplification testing of skin lesions and cultures of synovial fluid can establish the diagnosis. Blood cultures should also be obtained. About 20% of cases of tenosynovitis/dermatitis syndrome are proven based on a compatible clinical presentation with identification of gonococci on testing of blood, synovial fluid, or skin. About 80% of cases are classified as probable based on finding gonococci in a mucosal site specimen (but not from blood or another sterile site) or documenting that a sex partner has gonococcal infection. A possible case of disseminated gonococcal infection has the compatible clinical presentation but no positive diagnostic tests from blood or any other sites tested. Disseminated gonococcal infections must be distinguished from other causes of fever and rash (Chapter 259), as well as other monoarticular or usually asymmetrical oligoarthritis (Chapter 236), including other types of septic arthritis (Chapter 251), as well as reactive arthritis, which can be triggered by sexually acquired chlamydial infection (Chapter 254) but, unlike gonococcal arthritis, frequently involves the axial skeleton.

TREATMENT

Treatment for gonococcal-related arthritis and arthritis-dermatitis syndrome is ceftriaxone (1 g IM or IV every 24 hours), with added doxycycline (100 mg orally twice daily for 7 days) if chlamydial infection cannot be excluded. The intravenous component should also be continued for a minimum of 7 days or until the patient is afebrile (whichever is longer) after which the patient may complete the 7-day course with an oral regimen (e.g., cefixime 400 mg orally twice daily).

For gonococcal meningitis and endocarditis, the recommended regimen is ceftriaxone (1 to 2 g IV every 24 hours) plus doxycycline (100 mg orally twice daily for 7 days) if chlamydial infection has not been excluded. The intravenous component should also be continued for a minimum of 7 days or until the patient is afebrile (whichever is longer). Alternatives to ceftriaxone are cefotaxime (1 g IV every 8 hours) or ceftizoxime (1 g IV every 8 hours). Intravenous treatment should be for 10 to 14 days for meningitis and 4 or more weeks for endocarditis and osteomyelitis.

Gonococcal septic arthritis infections require drainage (Chapter 251), similar to staphylococcal arthritis. About 50% of cases of gonococcal endocarditis require valve replacement.

PROGNOSIS

Many cases clear spontaneously. Most patients with the tenosynovitis/dermatitis syndrome resolve their symptoms spontaneously or quickly with antibiotics, but some cases progress to septic arthritis. For gonococcal endocarditis and meningitis, mortality can be as high as 20%.

PREVENTION

The sexual transmission of *N. gonorrhoeae* can be greatly reduced by changes in sexual practices, including the use of condoms during oral, anal, or vaginal intercourse. Complications may also be reduced by screening to detect infectious individuals. In high-income settings, the routine screening of pregnant women and the preventive application of ocular antibacterial ointment at birth has essentially eliminated ophthalmic neonatorum, but it remains a problem in some resource-limited countries.

Screening

Based on substantial evidence,[A4] the United States Preventive Services Task Force recommends annual screening for gonorrhea to prevent complications such as pelvic inflammatory disease in all sexually active females younger than age 25 years and in females with increased risk for infection ages 25 years and older.[21] The U.S. Centers for Disease Control and Prevention (CDC) recommends screening men who have sex with men at least annually (and every 3 to 6 months if at increased risk) at all anatomic sites of exposure. Routine screening is not routinely recommended for males who are exclusively heterosexual and do not live in correctional settings.

Barrier Methods

Male and female condoms are highly effective barriers that reduce the likelihood of exposure and transmission. For condoms to be effective at reducing the transmission of gonorrhea, they must be used correctly and consistently. Clinicians should assure that both male and female patients understand the different types of condoms and how to use them correctly. Persons who practice using condoms and carry condoms with them are more likely to use them. Female condoms offer a female-controlled way to prevent gonorrhea and reduce a female's dependency on a male partner. Female condoms may also be safely used for receptive anal sex by both males and females.

Behavioral Intervention

Factors that put persons at increased risk for sexually transmissible infections include alcohol and substance use disorders, poverty, stigma, and governmental and institutional policies that discriminate based on gender, race, ethnicity, sexual orientation, and gender identity. Successful interventions to reduce individual risk must occur at the individual, community, and policy level. Individual-level behavioral counseling can reduce the risk for sexually transmitted infections.[22]

Microbial Prophylaxis and Vaccination

Antimicrobial pre-exposure or post-exposure prophylaxis may be partially efficacious against *N. gonorrhoeae* in sexually active adults. Furthermore, antiseptic mouthwash is not effective for preventing oropharyngeal infection.[A5] Epidemiologic data suggest that outer-membrane-vesical–containing meningococcal type B vaccines can reduce the rate of acquisition of gonorrhea by 30 to 40%.[23]

276 CHANCROID

STANLEY M. SPINOLA

DEFINITION

Chancroid is a sexually transmitted disease that is characterized by painful genital ulcers and inguinal lymphadenitis caused by *Haemophilus ducreyi*. *H. ducreyi* also is a major cause of nonsexually transmitted cutaneous ulcers in children who live in regions of the South Pacific and Africa where yaws (Chapter 295), which is a nonsyphilitic treponematosis that causes a disfiguring and debilitating childhood infectious disease, is endemic.

H. ducreyi is a gram-negative coccobacillus that is not a true *Haemophilus* species. Within the Pasteurellaceae, *H. ducreyi* is grouped in a distinct lineage with *Mannheimia haemolytica* and *Aggregatibacter* (formerly *Actinobacillus*) *pleuropneumoniae*. *H. ducreyi* is likely to have diverged from these animal respiratory pathogens to occupy its niche in the human epithelium.

EPIDEMIOLOGY

Chancroid, which is endemic in resource-poor regions of Africa and Asia, facilitates the transmission of human immunodeficiency virus (HIV-1). In the 1990s, the World Health Organization estimated the annual global prevalence of chancroid to be 4 to 6 million cases. Because of the widespread use of syndromic management, which consists of treatment for syphilis and chancroid without diagnostic testing, the prevalence of chancroid has dramatically declined in endemic areas. Chancroid can be maintained only in networks with high rates of multiple sex partners. Infected female sex workers play an important role in its epidemiology, and targeted treatment of sex workers can eradicate the disease in endemic areas. Despite these successes, chancroid persists in many

ABSTRACT

Haemophilus ducreyi is a gram-negative facultative anaerobic bacterium that causes chancroid, which is a genital ulcer disease that is endemic in Africa and Asia and that facilitates transmission of HIV-1. *H. ducreyi* is sexually transmitted but is also a major cause of nonsexually transmitted cutaneous ulcers in children in yaws-endemic countries of Africa and the South Pacific islands. In chancroid, infected female sex workers serve as a reservoir for *H. ducreyi*, and transmission is thought to occur via microabrasions during intercourse. In cutaneous ulcers, asymptomatic colonization of the skin, flies, and fomites provide environmental reservoirs that allow the bacterium to cause infection following minor skin trauma. In genital ulcers, *H. ducreyi* is frequently cotransmitted with herpes simplex virus and *Treponema pallidum*, the causative agent of syphilis. In cutaneous ulcers, coinfection is common with *Treponema pallidum* subsp. pertenue, which is the causative agent of yaws. Although genital and cutaneous ulcers caused by *H. ducreyi* are typically nonindurated and very painful with ragged edges, clinical diagnosis is unreliable, so definitive diagnosis requires either a positive culture or polymerase chain reaction test. The most reliable treatment regimens are macrolides, quinolones, or third-generation cephalosporins.

countries, thereby implying a reservoir of untreated sex workers. Although urban outbreaks of chancroid associated with sex work occurred in the United States in the 1980s and 1990s, only 3 to 11 cases were reported annually from 2015 to 2019, most likely imported after contact with infected persons in endemic areas.

The male-to-female ratio of chancroid is 3:1, in part because of infection of multiple partners by sex workers. However, human inoculation experiments indicate that men are twice as susceptible as women to develop pustules, thereby suggesting that gender plays a role in the predominance of disease in men.

In yaws-endemic countries, *H. ducreyi* causes a chronic limb ulceration syndrome that occurs primarily in children.[1,2] Close contact of family members with ulcer cases is implicated in transmission. In yaws-endemic villages in Papua New Guinea, the prevalence of this syndrome has been 2 cases per 100 persons, and *H. ducreyi* is more common than *T. pallidum* subsp. *pertenue* in this setting. The overall prevalence of *H. ducreyi* infection in children aged 5 to 15 years can be as high as 7%. Similar data are reported from Ghana, the Solomon Islands, and Vanuatu, which together with Papua New Guinea are reported to have the highest prevalence of yaws. Travelers to endemic areas can acquire limb ulcers following minor trauma; the first case of cutaneous ulcers caused by *H. ducreyi* in the Netherlands was reported in 2018 in a person who imported it from Indonesia.[3]

PATHOBIOLOGY

In human inoculation experiments, puncture wounds are required to initiate infection, and the estimated infectious dose is as low as one bacterium. Papules develop within 24 hours and either spontaneously resolve or evolve into pustules in 2 to 5 days. Neutrophils and macrophages surround the organism and form an abscess that erodes the epidermis. Below the abscess is a collar of macrophages and regulatory T cells and a dermal infiltrate of macrophages, CD4 and CD8 T cells, natural killer cells, and dendritic cells. This histopathology, which resembles a suppurative granuloma, is associated with neutrophils and macrophages that fail to ingest the organism.

Whole-genome sequencing suggests cutaneous ulcer strains diverged from multiple lineages of genital ulcer strains during the past 180,000 years. RNA sequencing and metabolomics show that *H. ducreyi* changes its gene expression to adapt to the anaerobic, glucose-poor environment of the abscess and to scavenge alternative carbon sources, such as ascorbic acid.[4] Differential host susceptibility is associated with distinct dendritic cell responses, which may shape the responses of T cells and natural killer cells, and thereby influence the ability of phagocytes to ingest the organism.

CLINICAL MANIFESTATIONS

To cause chancroid, *H. ducreyi* is thought to enter the skin when breaks in the epithelium occur during intercourse. Papules, which form within hours to days, evolve into pustules in 2 to 3 days. After a few days to 2 weeks, the pustules ulcerate. Patients typically develop one to four painful ulcers (Fig. 276-1) but often do not seek treatment until they have had ulcerative symptoms for 1 to 3 weeks. By this time, 10 to 40% have suppurative inguinal lymphadenopathy or buboes (see Fig. 276-1).

Ulcers are classically very painful and nonindurated, with ragged edges. The ulcer, which may be covered by a yellow or gray necrotic exudate, bleeds when scraped. However, this presentation occurs in a minority of patients, and chancroid is frequently indistinguishable from syphilis (Chapter 295) and genital herpes simplex (Chapter 345).[5] Lesions in men are usually on the foreskin, coronal sulcus, or penile shaft. Lesions in women are usually on the labia, but women may have painless internal vaginal and cervical ulcers. Lesions also occur on the thighs and buttocks or at distant sites. These extragenital lesions are thought to be due to autoinoculation. Untreated, chancroid persists for months and causes giant ulcers, erosion of the infected area, or fibrosis, thereby leading to phimosis in men.

Although cutaneous ulcers occur in adults, they primarily occur in children on the lower legs (Fig. 276-2). Up to 20% of asymptomatic children in endemic areas are colonized by *H. ducreyi* on their skin, and it is likely that the organism enters and infects the skin via minor traumatic wounds. Ulcers due to *H. ducreyi* tend to be more tender, smaller, and less circular with less indurated edges than those due to yaws or dual infections, but there is a great deal of clinical overlap.

DIAGNOSIS

Clinical diagnosis is neither sensitive (about 70%) nor specific (about 55%),[6] so the definitive diagnosis of chancroid or cutaneous ulcers requires either a positive culture or a polymerase chain reaction (PCR) test. PCR has a sensitivity of 95 to 98% and a specificity of 99% for *H. ducreyi*[7,8] but is not commercially available. In comparison, the sensitivity for culture is approximately 75%.

FIGURE 276-1. Typical chancroidal ulcer and lymphadenitis in a man. (From Herpes-Coldsores.com. http://www.herpes-coldsores.com/std/chancroid_pictures.htm.)

Most sexually transmitted disease clinics do not routinely test patients for chancroid, so the diagnosis is typically made by the exclusion of genital herpes (Chapter 345) and syphilis (Chapter 295). Public health authorities should be notified so that specific diagnostic testing can be initiated in patients who have genital ulcers and lymphadenitis or who do not respond to treatment for primary syphilis.

The differential diagnosis (Chapter 264) of chancroid includes syphilis (Chapter 295), genital herpes (Chapter 345), lymphogranuloma venereum (Chapter 294), and granuloma inguinale (Chapter 292). Mixed infections with herpes simplex virus or syphilis occur in approximately 15 to 20% of cases of chancroid diagnosed by PCR. Patients with suspected chancroid should be tested for genital herpes, have serologic tests for syphilis and HIV-1, and have a dark-field examination.

For cutaneous ulcers, the differential diagnosis includes yaws (Chapter 295), *T. pallidum* subsp. *pertenue*, *Streptococcus pyogenes*, and *Fusobacteria*.[9] PCR testing, when available, is usually diagnostic.

TREATMENT

Because of syndromic management, little is known about the current prevalence of antibiotic resistance in *H. ducreyi*, but the only reliable treatment regimens are macrolides, quinolones, and third-generation cephalosporins.[A1] Current treatment recommendations for chancroid include single-dose azithromycin (1 g orally or ceftriaxone 250 mg intramuscularly), ciprofloxacin (500 mg orally twice a day for 3 days), and erythromycin base (500 mg orally three times a day for 7 days). Children with cutaneous ulcers respond to single-dose azithromycin (30 mg/kg orally).

In patients who are coinfected with HIV, chancroid ulcers may not heal as readily after antibiotic treatment with single-dose regimens. Multidose regimens are recommended if close follow-up cannot be ensured and may be considered in uncircumcised men, who are at higher risk for failure to respond to single-dose regimens. Repeated aspiration of buboes may be required to effect a cure. Incision and drainage is even more effective but is usually avoided because it can cause excessive scarring, especially keloid formation in Black patients.

PROGNOSIS

Clinical cure correlates with a reduction in pain and purulence, as well as re-epithelialization of the ulcer within 7 days. Patients who do not show improvement within 7 days should be regarded as treatment failures and given an alternative agent. Even if *H. ducreyi* is eradicated, ulcers may persist if genital

FIGURE 276-2. Cutaneous ulcer due to *Haemophilus ducreyi* in a child in Papua New Guinea. (Courtesy of Oriol Mitja.)

herpes or syphilis is present and not treated. Most ulcers heal in 2 weeks; large ulcers may take 4 weeks to heal. The same principles seem to apply to cutaneous ulcers.

PREVENTION

Circumcision reduces the risk of chancroid in men. Condoms are likely to be protective. Although several antibodies that may afford protection have been identified in animal models, no vaccine is currently available. Contacts of patients with chancroid should be treated with an approved regimen. Prevention of cutaneous ulcers is under investigation and likely will involve improved sanitation and hygiene.

277 *HAEMOPHILUS* AND *MORAXELLA* INFECTIONS

MONICA M. FARLEY

HAEMOPHILUS INFLUENZAE

DEFINITION

Haemophilus refers to the bacteria's requirement for specific blood components for growth. In the respiratory tract, which is the primary site of colonization for most *Haemophilus* species, the most common infections include otitis media, sinusitis, bronchitis, and pneumonia. Serious invasive diseases (e.g., epiglottitis, bacteremia, endocarditis, meningitis, septic arthritis) may occur, particularly in susceptible older adults and infants (Table 277-1).

TABLE 277-1 SITES OF COLONIZATION AND INFECTIONS BY *HAEMOPHILUS INFLUENZAE*

SPECIES	NORMAL FLORA	ASSOCIATED DISEASES
H. influenzae	Nasopharynx Upper respiratory tract	Meningitis Epiglottitis Sinusitis Otitis media Pneumonia Cellulitis Septic arthritis Osteomyelitis Obstetric infections Endocarditis
H. influenzae, biogroup *aegyptius*		Purulent conjunctivitis Brazilian purpuric fever

The Pathogen

Haemophilus species are small, nonmotile, pleomorphic, gram-negative bacteria that can grow aerobically or anaerobically. *H. influenzae* are classified or typed based on the presence or absence of serologically unique capsule polysaccharides—including six capsule serotypes (a to f) as well as nonencapsulated (nontypeable) forms. Encapsulated types are relatively clonal, whereas nonencapsulated types are very heterogeneous. Isolation of *Haemophilus* species in the laboratory is best accomplished on chocolate agar medium, which supplies the hemin and nicotinamide adenine dinucleotide required for its growth, in a carbon dioxide–enriched atmosphere.

EPIDEMIOLOGY

H. influenzae can colonize the nasopharynx of both children and adults. Current vaccination rates for *H. influenzae* type b are about 70% worldwide, but the organism still causes an estimated 3 million cases of serious disease and 400,000 deaths annually.

Prior to the introduction of *H. influenzae* type b conjugate vaccines in the United States, between 3 and 5% of infants harbored *H. influenzae* type b in their nasopharynx, and about 1 in 200 children less than 5 years of age experienced invasive disease. In unvaccinated populations, *H. influenzae* type b is still the most common cause of meningitis in young children,[1] but vaccines reduce invasive *H. influenzae* type b disease by more than 99%. Furthermore, the risk of secondary invasive infections among nonimmune household contacts of a patient with invasive *H. influenzae* type b disease is increased about 600-fold.

With immunization with a protein conjugate *H. influenzae* type b vaccine, both colonization and infection with *H. influenzae* type b are greatly reduced.[2] Although nasopharyngeal colonization with nontypeable *H. influenzae* is very common in both children and adults, infection occurs in only a small proportion of colonized individuals.

In the United States, the overall annual incidence of invasive *H. influenzae* infections is now 1.70 cases per 100,000 population, with cases increasing for *H. influenzae* types a, e, and f and nontypeable species[3] even as cases of type b have remained low. From 1998 to 2007, *H. influenzae* caused 6% of meningitis cases in U.S. adults, the majority of which were nontypeable strains. Similar data are reported from other countries where conjugate *H. influenzae* vaccines are routinely used.

The risk of invasive *H. influenzae* disease is highest in infants less than 1 year of age and adults ages 65 years and older.[4] People living with human immunodeficiency virus (HIV) infection also have increased risk for *H. influenzae* infection. Other underlying conditions that increase the risk for *H. influenzae* infection include immunoglobulin deficiencies (Chapter 231), sickle cell disease (Chapter 149), anatomic or functional asplenia (Chapter 154), malignant disease, pregnancy, cerebrospinal fluid (CSF) leaks, head trauma (Chapter 368), alcohol use disorders (Chapter 364), and chronic obstructive pulmonary disease (COPD; Chapter 76).

Disproportionately high rates of invasive *H. influenzae* disease also are noted in Indigenous populations. The incidence of invasive *H. influenzae* serotype a disease is currently 17 times higher in American Indian/Alaska native children below age 5 years than among children of all other races combined.[5] In nonvaccinated

herpes or syphilis is present and not treated. Most ulcers heal in 2 weeks; large ulcers may take 4 weeks to heal. The same principles seem to apply to cutaneous ulcers.

PREVENTION

Circumcision reduces the risk of chancroid in men. Condoms are likely to be protective. Although several antibodies that may afford protection have been identified in animal models, no vaccine is currently available. Contacts of patients with chancroid should be treated with an approved regimen. Prevention of cutaneous ulcers is under investigation and likely will involve improved sanitation and hygiene.

277 *HAEMOPHILUS* AND *MORAXELLA* INFECTIONS

MONICA M. FARLEY

HAEMOPHILUS INFLUENZAE

DEFINITION

Haemophilus refers to the bacteria's requirement for specific blood components for growth. In the respiratory tract, which is the primary site of colonization for most *Haemophilus* species, the most common infections include otitis media, sinusitis, bronchitis, and pneumonia. Serious invasive diseases (e.g., epiglottitis, bacteremia, endocarditis, meningitis, septic arthritis) may occur, particularly in susceptible older adults and infants (Table 277-1).

TABLE 277-1 SITES OF COLONIZATION AND INFECTIONS BY *HAEMOPHILUS INFLUENZAE*

SPECIES	NORMAL FLORA	ASSOCIATED DISEASES
H. influenzae	Nasopharynx Upper respiratory tract	Meningitis Epiglottitis Sinusitis Otitis media Pneumonia Cellulitis Septic arthritis Osteomyelitis Obstetric infections Endocarditis
H. influenzae, biogroup *aegyptius*		Purulent conjunctivitis Brazilian purpuric fever

The Pathogen

Haemophilus species are small, nonmotile, pleomorphic, gram-negative bacteria that can grow aerobically or anaerobically. *H. influenzae* are classified or typed based on the presence or absence of serologically unique capsule polysaccharides—including six capsule serotypes (a to f) as well as nonencapsulated (nontypeable) forms. Encapsulated types are relatively clonal, whereas nonencapsulated types are very heterogeneous. Isolation of *Haemophilus* species in the laboratory is best accomplished on chocolate agar medium, which supplies the hemin and nicotinamide adenine dinucleotide required for its growth, in a carbon dioxide–enriched atmosphere.

EPIDEMIOLOGY

H. influenzae can colonize the nasopharynx of both children and adults. Current vaccination rates for *H. influenzae* type b are about 70% worldwide, but the organism still causes an estimated 3 million cases of serious disease and 400,000 deaths annually.

Prior to the introduction of *H. influenzae* type b conjugate vaccines in the United States, between 3 and 5% of infants harbored *H. influenzae* type b in their nasopharynx, and about 1 in 200 children less than 5 years of age experienced invasive disease. In unvaccinated populations, *H. influenzae* type b is still the most common cause of meningitis in young children,[1] but vaccines reduce invasive *H. influenzae* type b disease by more than 99%. Furthermore, the risk of secondary invasive infections among nonimmune household contacts of a patient with invasive *H. influenzae* type b disease is increased about 600-fold.

With immunization with a protein conjugate *H. influenzae* type b vaccine, both colonization and infection with *H. influenzae* type b are greatly reduced.[2] Although nasopharyngeal colonization with nontypeable *H. influenzae* is very common in both children and adults, infection occurs in only a small proportion of colonized individuals.

In the United States, the overall annual incidence of invasive *H. influenzae* infections is now 1.70 cases per 100,000 population, with cases increasing for *H. influenzae* types a, e, and f and nontypeable species[3] even as cases of type b have remained low. From 1998 to 2007, *H. influenzae* caused 6% of meningitis cases in U.S. adults, the majority of which were nontypeable strains. Similar data are reported from other countries where conjugate *H. influenzae* vaccines are routinely used.

The risk of invasive *H. influenzae* disease is highest in infants less than 1 year of age and adults ages 65 years and older.[4] People living with human immunodeficiency virus (HIV) infection also have increased risk for *H. influenzae* infection. Other underlying conditions that increase the risk for *H. influenzae* infection include immunoglobulin deficiencies (Chapter 231), sickle cell disease (Chapter 149), anatomic or functional asplenia (Chapter 154), malignant disease, pregnancy, cerebrospinal fluid (CSF) leaks, head trauma (Chapter 368), alcohol use disorders (Chapter 364), and chronic obstructive pulmonary disease (COPD; Chapter 76).

Disproportionately high rates of invasive *H. influenzae* disease also are noted in Indigenous populations. The incidence of invasive *H. influenzae* serotype a disease is currently 17 times higher in American Indian/Alaska native children below age 5 years than among children of all other races combined.[5] In nonvaccinated

ABSTRACT

Haemophilus influenzae is a respiratory pathogen that may also cause significant invasive disease such as bacteremia, epiglottitis, meningitis, and other serious infections. Since the introduction of *Haemophilus influenzae* capsule type b (Hib) conjugate vaccines, *Haemophilus* b disease has declined significantly, but infections due to nontypeable (nonencapsulated) and other capsular serotypes have increased. Other *Haemophilus* spp that can cause serious infections include *H. parainfluenzae* and *H. ducreyi*. *Moraxella catarrhalis* is associated with upper respiratory infections and bronchitis but less commonly with invasive disease.

populations, daycare attendance, crowding, other siblings in the household, prior hospitalizations, and prior otitis media increase the risk for *H. influenzae* type b disease in young children, whereas breast-feeding decreases the risk.

PATHOBIOLOGY

H. influenzae have six unique polysaccharide capsular serotypes (a through f) that are key factors in virulence by inhibiting opsonization, clearance, and intracellular killing of the organisms. Nontypeable strains lack this capsular polysaccharide. The *H. influenzae* type b capsule contains pentose polysaccharides, specifically polyribosyl ribitol phosphate, whereas the other serotypes contain hexose polysaccharides. *H. influenzae* type b capsule is more virulent than the other capsulated types, and the amount of polyribosyl ribitol phosphate produced is related to its resistance to complement.

Structurally and antigenically distinct encapsulated isolates (types a to f) are responsible for most of the invasive infections in unvaccinated children and of acute epiglottitis in both children and adults, whereas the nonencapsulated (nontypeable) isolates are associated with localized respiratory mucosal infections, conjunctivitis, female genital tract infections, and invasive disease in older adults and in patients who have underlying conditions such as COPD. Nontypeable *H. influenzae* is one of the most common causes of acute otitis media in children. Among non-b capsule serotypes, serotype a capsule is most similar to the type b capsule, and type a isolates can cause severe invasive disease that is similar to *H. influenzae* type b in young children. In vaccinated populations, most infections are now caused by nontypeable strains and somewhat less often by non-b serotypes (particularly *H. influenzae* serotypes a, e, and f).

Fimbriae are present in both typeable and nontypeable isolates and are important virulence factors that facilitate adherence of *H. influenzae* to mucosal surfaces. The lipooligosaccharides of *H. influenzae* also contribute to their virulence. Phase-variable modifications to the *H. influenzae* surface lipooligosaccharide alter receptor tropism and evasion of innate immune defenses. Nontypeable *H. influenzae*, with lipopolysaccharides containing more phosphorylcholine, more efficiently colonize the upper respiratory tract by binding to platelet-activating factor receptors on epithelial cells. In contrast, isolates that invade the blood stream have lipopolysaccharides that contain less phosphorylcholine to avoid complement activation and enhance their intravascular survival.[6]

A variety of outer membrane proteins also serve as virulence factors in *H. influenzae* disease by inhibiting complement killing and facilitating mucosal adhesion. Effective activation of complement is an essential component of the host defense against some *H. influenzae* diseases, and congenital complement component deficiencies (e.g., in C2, C3, and factor I; see Chapter 37) increase the risk of serious infection. Efficient scavenging of iron within the human host is crucial for *H. influenzae* to multiply. To evade the local mucosal immune response, *H. influenzae* produces immunoglobulin A1 protease, which specifically cleaves human immunoglobulin A1 (IgA1).

Serum bactericidal antibodies directed against the polysaccharide capsule are critical to protection against encapsulated *H. influenzae*, particularly type b infection. Capsule-specific antibodies facilitate opsonization and complement-mediated killing. Neonates acquire transplacental maternal antibodies that protect against invasive Hib disease for the first 3 to 6 months of life. As maternal antibodies wane, susceptibility to *H. influenzae* type b infections increases during infancy. In unvaccinated populations, most cases of *H. influenzae* type b meningitis occur in infants after they lose passively acquired maternal antibodies and before they develop active humoral immunity. Not surprisingly, patients who have functional asplenia (e.g., sickle cell disease) or who have undergone splenectomy also have an increased risk of developing severe disease with *H. influenzae* type b and, rarely, serotype a.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Meningitis

H. influenzae meningitis now more commonly occurs in unvaccinated or undervaccinated young children, immunocompromised children and adults, and patients who have a history of skull fractures or CSF leaks.[7] As with other bacterial meningitides (Chapter 381), patients typically present with fever, headache, and mental status changes, including lethargy, confusion, somnolence, and sometimes seizures.

The CSF white blood cell count is usually greater than 1000/μL, with an elevated protein level and low glucose level. The CSF Gram stain is neither sensitive for detecting nor specific for excluding *H. influenzae*, and the diagnosis is established by CSF culture or a multiplex polymerase chain reaction (PCR) panel that detects *H. influenzae* nucleic acid, even in patients who have had prior antibiotic treatment, before culture results are available.

Epiglottitis

H. influenzae type b is the most common cause of acute epiglottitis in unvaccinated children, especially before age 5 years, but is rare after vaccination.[8] Symptoms in children include the rapid onset of fever, drooling, dysphagia, respiratory distress, stridor, and life-threatening airway obstruction. In adults, symptoms may be more insidious and include fever, sore throat, dysphagia, and odynophagia. Tender cervical lymphadenopathy is common in all ages. A swollen, cherry-red epiglottis (see Fig. 331-2B) can be visualized on laryngoscopy, which should be performed only by experts who can perform emergency tracheotomy if the procedure precipitates acute airway obstruction. A lateral radiograph (see Figs. 331-2 C and D) or a computed tomographic (CT) scan of the neck may confirm the diagnosis. *H. influenzae* should be differentiated from parainfluenza virus (Chapter 331), which is the leading cause of epiglottitis in vaccinated populations. Since *H. influenzae* is often part of the normal respiratory flora, PCR and cultures of the pharynx and other mucosal surfaces may not provide a definitive diagnosis, so the diagnosis is usually established by a positive blood culture for *H. influenzae*.

Tracheobronchitis

H. influenzae tracheobronchitis (Chapter 84), which is characterized by fever, cough, and purulent sputum without radiographic evidence of pneumonia, occurs especially as an exacerbation of respiratory symptoms in patients with known COPD.[9] A sputum Gram stain that demonstrates purulence and a predominance of small, pleomorphic/coccobacillary gram-negative organisms is suggestive of the diagnosis, but definitive bacteriologic diagnosis is often difficult to achieve, and associated bacteremia is rare. A response to treatment for *H. influenzae* supports the diagnosis.

Pneumonia

In vaccinated populations, *H. influenzae* pneumonia is seen predominantly in older adults, sometimes as a nosocomial infection, including ventilator-associated pneumonia (Chapters 85 and 261). Clinical features, which are typical of bacterial pneumonia in general (Chapter 85), include fever and productive cough, as well as signs and radiographic findings of lobar consolidation.[10] Pneumonia can be complicated by pleural effusions, abscess, empyema, and respiratory failure.

A predominance of gram-negative coccobacilli in purulent sputum suggests the diagnosis, but isolation of *H. influenzae* from sputum culture may also represent respiratory colonization. Isolation of *H. influenzae* from a normally sterile site such as blood or pleural fluid may establish the diagnosis. Most *H. influenzae* isolates that cause pneumonia in vaccinated populations are nontypeable, but serotype f has been associated with bacteremic pneumonia in adults.

Cellulitis

In unvaccinated children, a distinctive *H. influenzae* type b facial cellulitis is characterized by a blue or violaceous discoloration of the skin. However, other features (e.g., fever, erythema, and tenderness) may not be different than what is seen with cellulitis from other pathogens. The diagnosis is established by blood culture, tissue aspirate from the involved area, or both.

Sinusitis and Otitis Media

H. influenzae and *Streptococcus pneumoniae* (Chapter 268) are the most common bacterial isolates obtained by needle aspiration or surgery from patients with acute sinusitis (Chapter 394).[11] The *H. influenzae* isolates are most often nontypeable.

H. influenzae, predominately nontypeable strains in vaccinated populations, is still the most common cause of otitis media (Chapter 394) in young children. Children with *H. influenzae* otitis media may experience significant ear pain or exhibit irritability. With *H. influenzae* type b, bacteremia and meningitis may complicate the otitis. Examination usually shows an inflamed, opaque, bulging, tympanic membrane. Perforation with drainage may occur. A bacteriologic diagnosis can be made by Gram stain, PCR, or culture of purulent fluid obtained by tympanocentesis.[12]

Gynecologic and Urologic Infection

Nontypeable *H. influenzae* cause tubo-ovarian abscesses and salpingitis (Chapter 264) in women. *H. influenzae* and *H. parainfluenzae* account for about 7% of cases of acute urethritis in men, possibly due to oral-genital sexual contact.

Bacteremia, Endocarditis, and Pericarditis

H. influenzae can cause primary bacteremia without an obvious source, mostly in patients with immunocompromising conditions, such as lymphoma, leukemia,

or alcohol use disorder. A careful clinical and laboratory evaluation should be pursued to avoid missing a life-threatening focal infection, especially occult meningitis or epiglottitis.

H. influenzae is an unusual cause of endocarditis (Chapter 61), which most often occurs in patients with preexisting valvular heart disease.[13] Patients are at high risk for valvular dysfunction and arterial emboli. Diagnosis is made by blood culture and echocardiography.

H. influenzae rarely causes primary pericarditis in adults, but pericarditis associated with contiguous spread from adjacent pneumonia may occur. Diagnosis is made by echocardiography, CT, and pericardiocentesis.

Septic Arthritis

Septic arthritis (Chapter 251) due to *H. influenzae* type b is common in unvaccinated children and young adults but rare in older adults. Clinical features are similar to other causes of pyogenic arthritis.[14] Cases may include polyarticular arthritis. Diagnosis is made by arthrocentesis, Gram stain, PCR, and culture of joint fluid.

Purulent Conjunctivitis and Brazilian Purpuric Fever

H. influenzae is the most common cause of bacterial conjunctivitis (Chapter 391) in children, and adults can be secondarily infected. *H. influenzae aegyptius* (Koch-Weeks bacillus) is a cause of epidemic purulent conjunctivitis, mostly in children and commonly in hot climates or in the summer season. Clinical manifestations include conjunctival erythema, edema, mucopurulent exudate, and discomfort in the eyes. A unique clone causes a severe invasive infection in infants and children, called Brazilian purpuric fever, which is characterized by petechial or purpuric skin lesions and vascular collapse occurring days to weeks after an initial episode of conjunctivitis.

TREATMENT

A third-generation cephalosporin such as ceftriaxone (adult dose, 1 to 2 g intravenously once daily or every 12 hours for meningitis) or cefotaxime (adult dose, 2 g intravenously every 6 hours) should be initiated as therapy in patients with proven or suspected *H. influenzae* meningitis, epiglottitis, pneumonia, or bacteremia and continued for 5 to 7 days (7 days for meningitis). Tracheobronchitis and otitis media are commonly treated with oral antibiotics such as amoxicillin-clavulanate (500 mg every 12 hours), levofloxacin (500 mg daily), and moxifloxacin (400 mg daily) for 5 to 7 days. For focal infections, such as pericarditis, septic arthritis, and sinusitis due to sinus obstruction, drainage of the infection is key to successful treatment.

PREVENTION

A three- or four-dose primary series and booster of a protein-conjugated *H. influenzae* type b vaccine (Chapter 15) generates an effective T-cell–dependent immune response in the most vulnerable infants and young children. These vaccines reduce or eliminate carriage of Hib in the nasopharynx, thereby reducing transmission and providing indirect protection to others who are not vaccinated.[15] Older children and adults with sickle cell disease, asplenia, HIV infection, deficiencies of antibodies or complement, or cancer undergoing chemotherapy or radiation therapy may be candidates for a single dose of vaccine if they have not completed a primary series and booster or had at least one dose after 14 months of age. For recipients of hematopoietic stem cell transplants, a three-dose series given 4 weeks apart starting 6 to 12 months after transplantation should be completed, regardless of prior vaccine history.

Antibiotic prophylaxis with rifampin (10 mg/kg once daily for 4 days to infants younger than 1 month, 20 mg/kg, up to a maximum of 600 mg once daily for 4 days, to older children and 600 mg/day for 4 days to adults) is recommended for all household members of a patient with invasive *H. influenzae* type b disease if there are any nonimmunized or underimmunized household contacts less than 4 years of age. Prophylaxis is not routinely recommended for contacts of patients who have nontypeable or non–type b *H. influenzae* disease, though some experts recommend rifampin prophylaxis for invasive *H. influenzae*–type a disease using the same dosing as for type b disease for all household contacts when at least one member of the household is less than 4 years of age or is immunocompromised.[16]

PROGNOSIS

For *H. influenzae* meningitis, mortality ranges from approximately 5 to 18% and is highest in adults with encapsulated *H. influenzae*. Permanent neurologic sequelae, including sensorineural hearing loss, may persist in as many as a third of patients who survive. In the United States, death from acute epiglottitis has essentially disappeared in the *H. influenzae* vaccination era.[17]

For tracheobronchitis and pneumonia, prognosis varies with the underlying health of the patient. The elderly, as well as patients with underlying lung disease, HIV, asplenia, immunosuppression, or multiple comorbid conditions, are at greatest risk for severe disease and worse outcomes. Invasive *H. influenzae* infection with nontypeable strains in pregnant women is associated with high rates of fetal loss and extreme prematurity. Cellulitis (Chapter 408) and sinusitis (Chapter 394) resolve with antibiotic therapy. Otitis also resolves with antibiotics and often without them (Chapter 394).

OTHER *HAEMOPHILUS* SPECIES

Haemophilus parainfluenzae, which is part of the normal microbiota of the mouth and pharynx, is associated with a variety of infections, including dental abscesses, brain abscess, epidural abscess, liver abscess, osteomyelitis, pneumonia, empyema, epiglottitis, peritonitis, septic arthritis, bacteremia, endocarditis[18] and male urethritis. Meningitis is a rare but serious manifestation of *H. parainfluenzae* infection in children and adults. *Haemophilus* species, including *H. parainfluenzae*, also are part of the HACEK (***H****aemophilus* species, ***A****ggregatibacter*, ***C****ardiobacterium hominis*, ***E****ikenella corrodens*, and ***K****ingella kingae*) group of small, fastidious organisms associated with subacute endocarditis (Chapter 61). *Haemophilus ducreyi* is the cause of chancroid (Chapter 276), which is a sexually transmitted infection that causes genital ulcer disease. Several former *Haemophilus* species also associated with endocarditis, including *H. aphrophilus*, *H. paraphrophilus*, and *H. segnis*, have been reclassified into the *Aggregatibacter* genus.

MORAXELLA INFECTIONS

DEFINITION

Moraxella catarrhalis is a respiratory pathogen associated with infections such as acute otitis media in children and exacerbations of chronic bronchitis in adults.

The Pathogen

Moraxella organisms are small, catalase- and oxidase-positive, gram-negative bacteria that may be grown in the laboratory on blood or chocolate agar. *M. catarrhalis* form diplococci that are morphologically quite similar to *Neisseria*, but other *Moraxella* species may appear as gram-negative coccobacilli on Gram stain. *M. catarrhalis* is the most important of this genus (Table 277-2).

EPIDEMIOLOGY AND PATHOBIOLOGY

M. catarrhalis is an exclusively human pathogen that is found predominantly in the respiratory tract. The frequency of colonization of the upper respiratory tract with *M. catarrhalis* may be as high as 75% in infants but decreases to <5% in adults. Infection is believed to result from contiguous spread of the organism from colonized respiratory sites, possibly due to introduction of more virulent strains to which the host lacks immunity. *M. catarrhalis* may be responsible for approximately 10% of all exacerbations of COPD (Chapter 76). Interestingly, the prevalence of clinical *M. catarrhalis* upper respiratory tract infection has declined since the introduction of the conjugated pneumococcal vaccines. *M. catarrhalis* is also the cause of about 15% of cases of acute and chronic otitis media in children.

M. catarrhalis, which is a common co-resident of respiratory secretions along with *H. influenzae*, releases biologically active outer membrane vesicles, which contain multiple virulence factors that contribute to the pathobiology of otitis media. The mechanism for coexistence of these pathogens may, in part,

TABLE 277-2 SITES OF COLONIZATION AND INFECTION BY *MORAXELLA* SPECIES

SPECIES	NORMAL FLORA	ASSOCIATED DISEASES
M. catarrhalis	Oral cavity and upper respiratory tract	Chronic bronchitis exacerbation Otitis media Pneumonia Sinusitis Bacteremia, endocarditis Arthritis, osteomyelitis, epiglottitis (all extremely rare)
M. lacunata	Upper respiratory tract	Chronic conjunctivitis, rare endocarditis, arthritis
Other *Moraxella*	Upper respiratory tract	Rare cases of bacteremia, endocarditis, arthritis, meningitis

be due to the capacity of *M. catarrhalis* outer membrane vesicles to inactivate complement, thereby enhancing survival of *H. influenzae*.

CLINICAL MANIFESTATIONS

M. catarrhalis can cause pneumonia, particularly in older adults with COPD and other underlying conditions such as diabetes mellitus. Bacteremic pneumonia is rare. Patient-to-patient spread has been demonstrated, and nosocomial pneumonia due to *M. catarrhalis* may occur.

Otitis media due to *M. catarrhalis* tends to be milder than that due to other pathogens, and complications such as spontaneous rupture of the tympanic membrane or mastoiditis are uncommon. The organism also causes sinusitis and is a rare cause of bacteremia,[19] endocarditis,[20] and other invasive infections in children and adults, typically in immunocompromised individuals.

Other *Moraxella* species rarely cause serious infections except in patients with complement deficiency, cancer, or other immune deficiencies. *M. lacunata* is associated with a chronic angular conjunctivitis.

TREATMENT

For most noninvasive *M. catarrhalis* infections, oral amoxicillin-clavulanate (usual adult dose, 500 mg every 12 hours), a second- or third-generation cephalosporin (e.g., cefuroxime 500 mg twice daily), or a non–β-lactam antibiotic such as a fluoroquinolone (e.g., levofloxacin 500 mg daily or moxifloxacin 400 mg daily) should be initiated and continued for 5 to 7 days. Susceptibility testing, other than to detect β-lactamase, usually is not performed.

PROGNOSIS

For patients who have pneumonia or exacerbations of chronic obstructive pulmonary disease (Chapter 76), the prognosis varies depending on the severity of the underlying disease. Patients who are immunocompromised or have advanced lung disease are at greatest risk of severe disease and worse outcomes. Otitis resolves with antibiotics and often without them (Chapter 394).

278 CHOLERA AND OTHER *VIBRIO* INFECTIONS

EDUARDO GOTUZZO AND CARLOS SEAS

CHOLERA

DEFINITION

Cholera is a dreaded epidemic diarrheal disease caused by *Vibrio cholerae* serogroup O1 and, since 1992, by the new serogroup O139. The disease is characterized by acute, large-volume watery diarrhea. In its more severe form, a person may be severely dehydrated and in hypovolemic shock; the patient may die in a matter of a few hours after contracting the infection if treatment is not provided.

The Pathogen

V. cholerae is a curved gram-negative bacillus that belongs to the family Vibrionaceae and shares common characteristics with the family Enterobacteriaceae. *V. cholerae* O1 can be classified into three serotypes according to the presence of somatic antigens and into two biotypes, classic and El Tor, according to specific phenotypic characteristics. There is no evidence of different clinical spectra among the three serotypes of *V. cholerae*. The classic biotype, responsible for the first six pandemics of cholera, causes an approximately equal number of symptomatic and asymptomatic cases, whereas the El Tor biotype causes more asymptomatic infections. The classic biotype is confined to the south of Bangladesh, and the El Tor biotype is responsible for the current pandemic. Variants of El Tor biotype, which share phenotypic features of both biotypes, are responsible for the current epidemics in Asia, Africa, and Latin America and may cause more severe disease. The O139 serogroup is composed of a variety of genetically diverse strains, both toxigenic and nontoxigenic; it is genetically closer to El Tor *V. cholerae*.

EPIDEMIOLOGY

Cholera has both a predisposition to cause epidemics with pandemic potential and an ability to remain endemic in all affected areas.

Cholera is endemic today in Africa, Asia, and Latin America. Seven pandemics have been registered in history since 1817; the most recent has lasted more than five decades since its recognition in Indonesia in 1961.[1] In Africa, cholera causes an estimated million or more cases annually, far more than the 70,000 or so reported cases, and nearly 40,000 annual deaths.[2] Although cholera mostly affects developing countries, several developed countries, such as the United States, Canada, and Australia, have reported indigenous and imported cases. The most recent epidemics occurred in Haiti in 2022 to 2023[3] and Yemen in 2016 and 2017. Fig. 278-1 shows the distribution of cholera in the world from 1989 to 2019.

People of all ages are at risk to contract the infection in epidemic settings, whereas children older than 2 years are mainly affected in endemic areas. *V. cholerae* lives in riverine, brackish, and estuarine ecosystems, where both O1 and non-O1 strains coexist, with non-O1 and nontoxigenic O1 strains predominating over toxigenic O1 strains. In its natural environment, *V. cholerae* lives attached to algae or to crustacean shells and copepods, with which it coexists in a symbiotic manner. Several conditions, such as temperature, salinity, and availability of nutrients, determine the survival of *V. cholerae*; when these conditions are adverse, vibrios survive in a viable but nonculturable state. Cholera phages modulate the abundance of *V. cholerae* in the environment and determine the beginning and end of epidemics. Phages may also play a role in the emergence of new *V. cholerae* serogroups by transferring genetic material to nontoxigenic strains.

From its aquatic environment, *V. cholerae* is introduced to humans through contamination of water sources and food.[4] Once humans are infected, very high attack rates may take place, particularly in previously naïve populations. The disease can be acquired by drinking contaminated water from rivers, ponds, lakes, and even tube well sources. Drinking unboiled water, introducing hands into containers used to store drinking water, drinking beverages from street vendors, drinking beverages with contaminated ice, and drinking water outside the home are risk factors. Drinking boiled water, acidic beverages, and carbonated water and using narrow-necked vessels for storing water are protective measures. Epidemics of cholera can be associated with the ingestion of leftover rice, raw fish, cooked crabs, seafood, raw oysters, and fresh vegetables and fruits.

Person-to-person transmission is less likely to occur because a large inoculum is necessary to transmit disease. Nevertheless, high transmission rates (approximately 50%) are reported among household contacts of patients with cholera in endemic areas.

Epidemics of cholera tend to occur during the hot season. Factors affecting climate change and climate variability have an impact on the incidence of cholera. The El Niño–Southern Oscillation, which is a periodic phenomenon representative of global climate variability, causes the warming of normally cool waters in the Pacific coastline of Peru, thereby promoting phytoplankton bloom, zooplankton bloom, and the proliferation of *V. cholerae*.

Some host factors are important in the transmission of cholera. The chronic gastritis associated with *Helicobacter pylori* (Chapter 125) predisposes to cholera by inducing hypochlorhydria, which reduces the ability of the stomach to contain the infection. Use of proton pump inhibitors or histamine-2 blockers and other conditions that cause achlorhydria also increase the risk. An unexplained predisposition to severe disease due to El Tor biotype in persons with the O blood group has been observed in Asia and more recently in Latin America. Innate predisposition has also been reported in endemic areas. Thus, complex associations among climatic, seasonal, bacterial, and human factors affect the transmission of cholera.

PATHOBIOLOGY

V. cholerae O1 and O139 cause clinical disease by secreting an enterotoxin that promotes the secretion of fluids and electrolytes by the small intestine. The infectious dose of bacteria varies with the vehicle. When water is the vehicle, more bacteria are needed to cause disease (10^3 to 10^8), but when the vehicle is food, lower amounts are needed (10^2 to 10^4).

be due to the capacity of *M. catarrhalis* outer membrane vesicles to inactivate complement, thereby enhancing survival of *H. influenzae*.

CLINICAL MANIFESTATIONS

M. catarrhalis can cause pneumonia, particularly in older adults with COPD and other underlying conditions such as diabetes mellitus. Bacteremic pneumonia is rare. Patient-to-patient spread has been demonstrated, and nosocomial pneumonia due to *M. catarrhalis* may occur.

Otitis media due to *M. catarrhalis* tends to be milder than that due to other pathogens, and complications such as spontaneous rupture of the tympanic membrane or mastoiditis are uncommon. The organism also causes sinusitis and is a rare cause of bacteremia,[19] endocarditis,[20] and other invasive infections in children and adults, typically in immunocompromised individuals.

Other *Moraxella* species rarely cause serious infections except in patients with complement deficiency, cancer, or other immune deficiencies. *M. lacunata* is associated with a chronic angular conjunctivitis.

TREATMENT

For most noninvasive *M. catarrhalis* infections, oral amoxicillin-clavulanate (usual adult dose, 500 mg every 12 hours), a second- or third-generation cephalosporin (e.g., cefuroxime 500 mg twice daily), or a non–β-lactam antibiotic such as a fluoroquinolone (e.g., levofloxacin 500 mg daily or moxifloxacin 400 mg daily) should be initiated and continued for 5 to 7 days. Susceptibility testing, other than to detect β-lactamase, usually is not performed.

PROGNOSIS

For patients who have pneumonia or exacerbations of chronic obstructive pulmonary disease (Chapter 76), the prognosis varies depending on the severity of the underlying disease. Patients who are immunocompromised or have advanced lung disease are at greatest risk of severe disease and worse outcomes. Otitis resolves with antibiotics and often without them (Chapter 394).

278 CHOLERA AND OTHER *VIBRIO* INFECTIONS

EDUARDO GOTUZZO AND CARLOS SEAS

CHOLERA

DEFINITION

Cholera is a dreaded epidemic diarrheal disease caused by *Vibrio cholerae* serogroup O1 and, since 1992, by the new serogroup O139. The disease is characterized by acute, large-volume watery diarrhea. In its more severe form, a person may be severely dehydrated and in hypovolemic shock; the patient may die in a matter of a few hours after contracting the infection if treatment is not provided.

The Pathogen

V. cholerae is a curved gram-negative bacillus that belongs to the family Vibrionaceae and shares common characteristics with the family Enterobacteriaceae. *V. cholerae* O1 can be classified into three serotypes according to the presence of somatic antigens and into two biotypes, classic and El Tor, according to specific phenotypic characteristics. There is no evidence of different clinical spectra among the three serotypes of *V. cholerae*. The classic biotype, responsible for the first six pandemics of cholera, causes an approximately equal number of symptomatic and asymptomatic cases, whereas the El Tor biotype causes more asymptomatic infections. The classic biotype is confined to the south of Bangladesh, and the El Tor biotype is responsible for the current pandemic. Variants of El Tor biotype, which share phenotypic features of both biotypes, are responsible for the current epidemics in Asia, Africa, and Latin America and may cause more severe disease. The O139 serogroup is composed of a variety of genetically diverse strains, both toxigenic and nontoxigenic; it is genetically closer to El Tor *V. cholerae*.

EPIDEMIOLOGY

Cholera has both a predisposition to cause epidemics with pandemic potential and an ability to remain endemic in all affected areas.

Cholera is endemic today in Africa, Asia, and Latin America. Seven pandemics have been registered in history since 1817; the most recent has lasted more than five decades since its recognition in Indonesia in 1961.[1] In Africa, cholera causes an estimated million or more cases annually, far more than the 70,000 or so reported cases, and nearly 40,000 annual deaths.[2] Although cholera mostly affects developing countries, several developed countries, such as the United States, Canada, and Australia, have reported indigenous and imported cases. The most recent epidemics occurred in Haiti in 2022 to 2023[3] and Yemen in 2016 and 2017. Fig. 278-1 shows the distribution of cholera in the world from 1989 to 2019.

People of all ages are at risk to contract the infection in epidemic settings, whereas children older than 2 years are mainly affected in endemic areas. *V. cholerae* lives in riverine, brackish, and estuarine ecosystems, where both O1 and non-O1 strains coexist, with non-O1 and nontoxigenic O1 strains predominating over toxigenic O1 strains. In its natural environment, *V. cholerae* lives attached to algae or to crustacean shells and copepods, with which it coexists in a symbiotic manner. Several conditions, such as temperature, salinity, and availability of nutrients, determine the survival of *V. cholerae*; when these conditions are adverse, vibrios survive in a viable but nonculturable state. Cholera phages modulate the abundance of *V. cholerae* in the environment and determine the beginning and end of epidemics. Phages may also play a role in the emergence of new *V. cholerae* serogroups by transferring genetic material to nontoxigenic strains.

From its aquatic environment, *V. cholerae* is introduced to humans through contamination of water sources and food.[4] Once humans are infected, very high attack rates may take place, particularly in previously naïve populations. The disease can be acquired by drinking contaminated water from rivers, ponds, lakes, and even tube well sources. Drinking unboiled water, introducing hands into containers used to store drinking water, drinking beverages from street vendors, drinking beverages with contaminated ice, and drinking water outside the home are risk factors. Drinking boiled water, acidic beverages, and carbonated water and using narrow-necked vessels for storing water are protective measures. Epidemics of cholera can be associated with the ingestion of leftover rice, raw fish, cooked crabs, seafood, raw oysters, and fresh vegetables and fruits.

Person-to-person transmission is less likely to occur because a large inoculum is necessary to transmit disease. Nevertheless, high transmission rates (approximately 50%) are reported among household contacts of patients with cholera in endemic areas.

Epidemics of cholera tend to occur during the hot season. Factors affecting climate change and climate variability have an impact on the incidence of cholera. The El Niño–Southern Oscillation, which is a periodic phenomenon representative of global climate variability, causes the warming of normally cool waters in the Pacific coastline of Peru, thereby promoting phytoplankton bloom, zooplankton bloom, and the proliferation of *V. cholerae*.

Some host factors are important in the transmission of cholera. The chronic gastritis associated with *Helicobacter pylori* (Chapter 125) predisposes to cholera by inducing hypochlorhydria, which reduces the ability of the stomach to contain the infection. Use of proton pump inhibitors or histamine-2 blockers and other conditions that cause achlorhydria also increase the risk. An unexplained predisposition to severe disease due to El Tor biotype in persons with the O blood group has been observed in Asia and more recently in Latin America. Innate predisposition has also been reported in endemic areas. Thus, complex associations among climatic, seasonal, bacterial, and human factors affect the transmission of cholera.

PATHOBIOLOGY

V. cholerae O1 and O139 cause clinical disease by secreting an enterotoxin that promotes the secretion of fluids and electrolytes by the small intestine. The infectious dose of bacteria varies with the vehicle. When water is the vehicle, more bacteria are needed to cause disease (10^3 to 10^8), but when the vehicle is food, lower amounts are needed (10^2 to 10^4).

ABSTRACT

Cholera is a dreaded epidemic diarrheal disease caused by *Vibrio cholerae* serogroup O1 and, since 1992, by the new serogroup O139. The disease is characterized by acute watery diarrhea. In its more severe form, a person may be severely dehydrated and in hypovolemic shock; the patient may die in a matter of a few hours after contracting the infection if treatment is not provided. Cholera is endemic today in Africa, Asia, and Latin America. Seven pandemics have been registered in history since 1817; the most recent has lasted more than five decades since its recognition in Indonesia in 1961. Changes in the climate, the environment, and the pathogen have promoted transmission to humans. Diagnosis is suspected based on clinical presentation and confirmed by molecular methods or by isolation of *Vibrio* in culture. Treatment is based on replacing intestinal losses with rehydration solutions and, in severe cases, providing antimicrobials. Prevention includes implementing sanitation and hygiene as well as using licensed oral vaccines in endemic and epidemic settings.

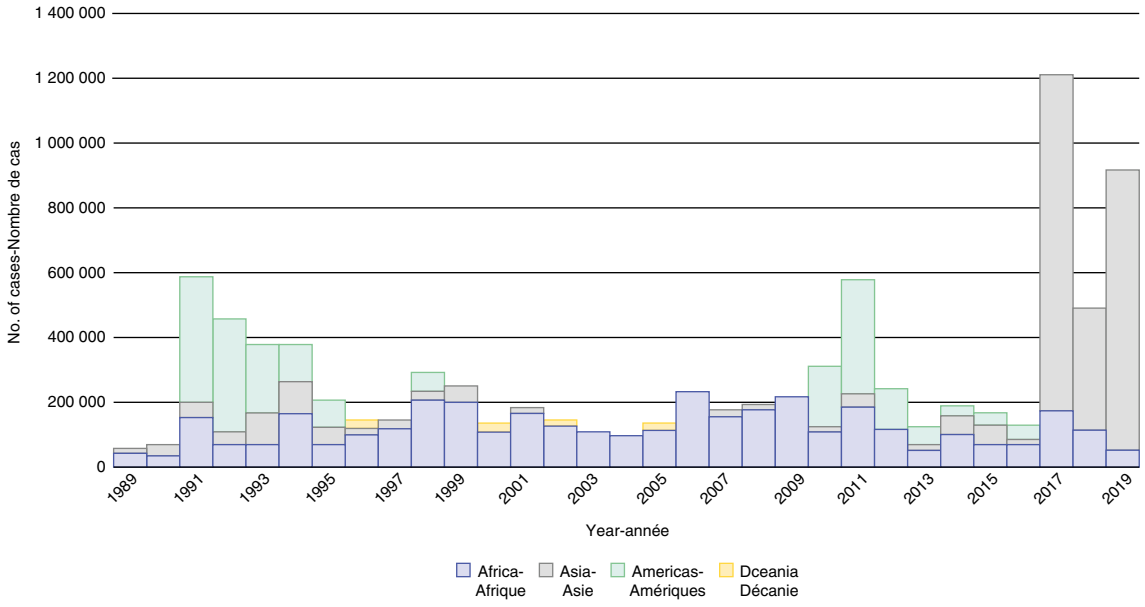

FIGURE 278-1. World distribution of cholera from 1989 to 2019 based on reports to the World Health Organization. (Reprinted with permission from the World Health Organization. Cholera, 2019. *Wkly Epidemiol Rec*. 2020;37:441-448.)

The genetic material of El Tor *V. cholerae* O1 is included in two circular chromosomes, the larger containing 3 megabases and the smaller containing 1.07 megabases. The main virulence genes are *ctxA* and *ctxB*, which encode cholera toxin subunits A and B, respectively, and *tcpA*, which codes for toxin coregulated pilus. Genes unique to El Niño–Southern Oscillation *V. cholerae* may encode specific features that allow this biotype to survive better in the environment as well as to be more infectious to humans.

Cholera toxin has two subunits, a pentamer B subunit and a monomer A subunit. The B subunit allows binding of the toxin to a specific receptor, which is a ganglioside (GM_1) located on the surface of cells lining the mucosa along the intestine of humans and certain suckling mammals. The active, or A, subunit has two components, A1 and A2, linked by a disulfide bond. Activation of adenylate cyclase by the A1 component increases cyclic adenosine monophosphate in intestinal epithelial cells, thereby blocking the absorption of sodium and chloride by microvilli and promoting the secretion of chloride and water by crypt cells. These events lead to the production of watery diarrhea with electrolyte concentrations similar to those of plasma (Table 278-1). Other toxins also have been isolated from pathogenic *V. cholerae*, but their roles in genesis of the disease are less clear.

CLINICAL MANIFESTATIONS

After an incubation period of 12 to 72 hours (median 1.4 days), symptomatic cholera is characterized by the abrupt onset of watery diarrhea, vomiting, generalized cramps, oliguria, and dehydration, which ranges from mild to severe and life-threatening.[5] Patients with mild dehydration cannot be differentiated from those infected by other enteric pathogens that cause watery diarrhea (Chapters 270, 279, 280, 284, and 285). In contrast, patients with severe dehydration secondary to cholera are easy to identify in that their stools have the appearance of rice water, and no other clinical illness produces such severe dehydration as quickly (in a matter of a few hours) as cholera.

Physical examination shows a feeble pulse, but fever is rarely present. Patients look anxious and restless. Their eyes are very sunken, their mucous membranes are dry, their skin has lost its elasticity and when pinched retracts very slowly, their voice may be almost nonaudible, and their intestinal sounds are prominent. Although watery diarrhea is the hallmark of cholera, some patients do not have diarrhea but instead have abdominal distention and ileus, a relatively rare type of cholera called cholera sicca.

Laboratory findings in patients with severe dehydration consist of an increase in hematocrit, urine specific gravity, and total serum protein; azotemia; metabolic acidosis with a high anion gap; normal or low serum potassium levels; and normal or slightly low sodium and chloride levels. The calcium and magnesium content in plasma is high as a result of hemoconcentration. Leukocytosis is observed in patients with severe cholera. Hyperglycemia, caused by high concentrations of epinephrine, glucagon, and cortisol stimulated by hypovolemia, is more commonly seen than hypoglycemia.

Acute renal failure, which is the most severe complication of cholera, has an incidence rate of about 10 cases per 1000. Patients with acute renal failure almost always have a history of improper rehydration.

Cholera carries a poor prognosis in pregnant women, who have more severe clinical illness, especially when it is acquired at the end of the pregnancy. Fetal loss occurs in as many as 50% of these pregnancies. Cholera in the elderly also carries a poor prognosis because of an increase in complications, particularly acute renal failure, severe metabolic acidosis, and pulmonary edema.

DIAGNOSIS

In the developing world, dark-field microscopy showing a high number of bacteria and chaotic bacterial movement in a stool sample from patients with diarrhea is characteristic of *V. cholerae* infection. Specific antisera against the serotype block the movement of vibrios and allow confirmation of the diagnosis. Under epidemic conditions, observing bacteria with a darting movement in a stool sample from a patient with suspected infection under dark-field microscopy is adequate to make the diagnosis.

Definitive confirmation can be achieved using DNA amplification by polymerase chain reaction (PCR) to detect vibrios in stool and environmental samples. A number of rapid tests have been developed, but few are suitable for public health purposes. The bacterium can also be identified in culture using a specific medium to isolate *V. cholerae* from stool.

TREATMENT

Rehydration

The objectives of therapy are to restore the fluid losses caused by diarrhea and vomiting, to correct the metabolic acidosis, to restore potassium deficits, and to replace continuous fluid losses.[6] Treatment of patients with milder forms of dehydration is easy, but treatment of patients with severe dehydration requires experience and proper training (Table 278-2).

Rehydration should be accomplished in two phases: the rehydration phase and the maintenance phase. The purpose of the rehydration phase is to restore normal intravascular volume, and it should last no longer than 4 hours.

The intravenous route should be restricted to patients who do not tolerate the oral route, patients who vomit more than 10 to 20 mL/kg/hour, and all patients with severe dehydration. Intravenous fluids should be infused at a total volume of 100 mL/kg during the rehydration phase in severely dehydrated patients. Lactated Ringer solution is preferred, but other solutions may be used as well (see Table 278-1).

Patients who do not have severe dehydration and who tolerate the oral route can be rehydrated with oral rehydration solutions exclusively and discharged promptly from the health center. Oral rehydration therapy uses the principle of common transportation of solutes, electrolytes, and water by the intestine not affected by cholera toxin. People with diarrhea can undergo successful rehydration with simple solutions containing glucose and electrolytes. The World Health Organization recommends an oral rehydration solution with reduced

TABLE 278-1 ELECTROLYTE COMPOSITION OF CHOLERA STOOLS AND SOLUTIONS RECOMMENDED FOR TREATMENT

	Na^+	Cl^-	K^+	HCO_3^-	GLUCOSE	OSMOLARITY
Stools of adults with severe cholera	130	100	20	44		
Intravenous lactated Ringer solution	130	109	4	28*	0	271
Intravenous normal saline	154	154	0	0	0	308
Standard oral rehydration solution promoted by the WHO	90	80	20	10†	111	311
Reduced-osmolarity oral rehydration solution promoted by the WHO	75	65	20	10†	75	245
Rice-based oral rehydration solution	90	80	20	10†		270

*Lactated Ringer solution contains citrate instead of bicarbonate.
†Bicarbonate is replaced by trisodium citrate.
Glucose concentration is in mg/dL, electrolyte concentrations are in mEq/L, and osmolarity is in mOsm/L.
Cl^- = chloride; HCO_3^- = bicarbonate; K^+ = potassium; Na^+ = sodium; WHO = Word Health Organization.

TABLE 278-2 RECOMMENDATIONS FOR TREATMENT OF CHOLERA PATIENTS

Determine the degree of dehydration on arrival.
Rehydrate the patient in two phases:
- Rehydration phase—lasts 2 to 4 hours
- Maintenance phase—lasts until the end of the diarrheal episode

Register and periodically review input and output in predesigned charts.
Use the intravenous route in the following situations:
- In all severely dehydrated patients, in whom the total volume to be infused during the rehydration phase is 100 mL/kg. For patients older than 1 year, 30 mL/kg should be infused in the first 30 minutes, the remaining 70 mL/kg should be infused in 2.5 hours. For children younger than 1 year, the first 30 mL/kg should be infused in 1 hour.
- Patients with some dehydration who are unable to tolerate the oral route
- Patients with high stool output (>10 mL/kg/hour) during the maintenance phase

Use oral rehydration solutions, glucose or rice-based, during the maintenance phase to match ongoing losses. Volumes of 800 to 1000 mL/hour are usually required. Low-osmolarity solutions are not recommended.
Start an oral antimicrobial agent in patients with severe cholera when full rehydration has been achieved and oral tolerance is confirmed. Single-dose doxycycline, 300 mg, is the preferred regimen. Erythromycin or a quinolone is a suitable alternative.
Discharge patients only if oral tolerance is adequate (≥1000 mL/hour), urine output is satisfactory (≥40 mL/hour), and stool volume is low (≤400 mL/hour).

Modified with permission from Seas C, DuPont HL, Valdez LM, et al. Practical guidelines for the treatment of cholera. *Drugs.* 1996;51:966-973.

osmolarity (245 mOsm/L) to treat all diarrheal diseases. This solution contains lower sodium than the standard oral rehydration solution (75 vs. 90 mEq/L) but does not increase the risk of symptomatic hyponatremia. The addition of L-histidine to rice-based oral rehydration solutions can reduce the volume and duration of diarrhea and the use of intravenous therapy in adults with cholera.

All signs of dehydration should have disappeared and the patient should pass urine at a rate of 0.5 mL/kg/hour or greater after the rehydration phase is finished. The maintenance phase follows immediately. During this phase, the objective is to maintain normal hydration status by replacement of ongoing losses. The oral route is preferred during this phase, and the use of oral rehydration solutions is highly recommended.

Antimicrobial Therapy

Effective antibiotics in patients with severe dehydration decrease the duration of diarrhea and the volume of stool by nearly half, but antimicrobial agents are not life-saving and always must be accompanied by fluid therapy. A single dose of oral doxycycline (300 mg) is the preferred regimen where sensitive strains predominate. Pregnant women can be treated with erythromycin (100 mg four times daily for 3 days) or furazolidone (500 mg four times daily for 3 days). Because of the emergence of resistance to tetracyclines and other antimicrobials in many endemic areas, other options are a single-dose of azithromycin (1 g or 20 mg/kg for smaller patients), a 3-day regimen with erythromycin (100 mg four times daily), a single-dose regimen of ciprofloxacin (1 g), or 3 days of norfloxacin (400 mg twice daily). The addition of oral zinc (30 mg/day) to an erythromycin regimen in children reduced the duration of diarrhea by 12%, with an additional 11% reduction in the volume of diarrhea in comparison to placebo. Antimotility agents such as loperamide or diphenoxylate, adsorbents, analgesics, antiemetics, and antisecretory drugs are not useful in patients with severe cholera.

PREVENTION

Access to potable water and ensuring proper management of excreta to avoid contamination of other water sources are important measures to reduce transmission of cholera. Alternative ways to prevent cholera transmission are necessary in developing countries. Water can be made safer to drink by boiling, adding chlorine, or filtering it with cloth made of cotton. Chemoprophylaxis of household contacts of cholera cases is not routinely recommended.

Two oral vaccines, the two-dose regimen of the inactivated vaccine WC-BS (whole cell plus B subunit) and a single dose of the live attenuated CVD 103-HgR vaccine, have been tested extensively in epidemic settings and in field trials in endemic areas. Parenteral vaccines are no longer recommended. Although the WC-BS vaccine elicits excellent immunogenicity[A1,A2] and shows good short-term protective efficacy (85% at 6 months), results at 3 and 5 years are less impressive (40% or less),[A3,A4] and children vaccinated below age 5 years have less protection after 3 years of receiving the vaccine compared with older children.[A5] Large studies have shown 80 to 90% efficacy, even during a cholera outbreak, and the potential to confer herd protection in the unvaccinated population. The live attenuated vaccine does not appear to be protective in an endemic setting. However, it is immunogenic and effective in adult travelers[7] and is licensed in the United States and Europe for this purpose.[8]

Indications for cholera vaccines include travel to endemic areas and situations in which high attack rates of cholera are expected, such as after environmental disasters, in refugee camps, and in urban slums in highly endemic areas. Complementary use of oral cholera vaccination, water sanitation, and hygienic interventions may have additive impact in endemic areas.[9] New oral vaccines, including both killed and live *Vibrio,* are being evaluated in endemic areas, with promising preliminary reports.

PROGNOSIS

Patients with severe cholera left untreated or improperly treated have a poor prognosis, with mortality rates higher than 50%. However, case-fatality rates during epidemics may be reduced to below 1% even in disaster situations, when adequate access to health care centers and proper management are provided. For example, mortality rates were extremely low during the Latin America epidemic in the 1990s, but rates of 19 to 35 deaths/1000 person-years were estimated during the epidemic in Haiti. Lack of treatment, delay in treatment, and not being managed in an established treatment center are also associated with increased mortality.

OTHER *VIBRIO* INFECTIONS

Noncholera vibrios, which have worldwide distribution and coexist in environments in which *V. cholerae* lives, cause a spectrum of clinical syndromes, including acute diarrhea, soft tissue infections, and sepsis,[10] especially in immunocompromised hosts. The CDC estimates about 80,000 cases of vibriosis annually in the United States, about two thirds of which are food-borne.[11]

Vibrio parahaemolyticus predominates (about 45% of isolates) but is associated with a case-fatality rate below 1%. In contrast, *Vibrio vulnificus* accounts for about 20% of the isolates but is associated with a case-fatality rate of about 30%. *Vibrio* illnesses in the United States are seasonal and peak during the summer. The incubation period for noncholeragenic *Vibrio* infection is usually 12 to 72 hours but can be as long as 1 week.

Nontoxigenic *Vibrio cholerae*

Nontoxigenic *V. cholerae* causes gastroenteritis, but unlike toxigenic *V. cholerae* O1 or O139, nontoxigenic *V. cholerae* does not cause epidemics. Illness ranges in severity from mild diarrhea to severe watery diarrhea. Fever and bloody diarrhea are unusual, but immunocompromised persons and those with liver disease can experience more severe illness, including fever, chills, and septic shock.

Infection with *Vibrio vulnificus*

V. vulnificus is associated with wound infections in persons in contact with contaminated water as well as with primary sepsis in immunocompromised hosts. This pathogen is responsible for 95% of seafood-related mortality in the United States. Wound infections follow trauma and are characterized by rapid progression of skin and soft tissue involvement, with necrosis and bulla formation occurring in more severe cases.[12] Fever, chills, and sepsis syndrome may ensue rapidly. Primary sepsis with bacteremia and metastatic lesions on the skin, characterized by disseminated erythematous lesions that may evolve to necrotic lesions, is a distinctive clinical manifestation in patients with chronic liver disease or alcohol dependence (Chapter 364) and in patients with blood disorders such as thalassemia (Chapter 148). Patients are acutely ill with high fever and must be managed aggressively with fluid resuscitation, surgical débridement, general supportive care, and antibiotic therapy. The recommended antibiotic therapy includes a combination of cefotaxime (2 g intravenously four times a day) plus doxycycline (100 mg orally two times a day). This combination is synergistic in vitro. Alternative antimicrobials are ceftazidime and ciprofloxacin in combination with doxycycline.

Infection with *Vibrio parahaemolyticus*

V. parahaemolyticus lives in marine environments and is a source of intestinal illness associated with the ingestion of contaminated shellfish, especially raw oysters.[13] Certain serovars have demonstrated pandemic spread (O3:K6 and O4:K68). The clinical illness may mimic cholera, but most cases are milder, with self-limited forms of acute watery diarrhea. *V. parahaemolyticus* also can cause wound infections, which are generally less severe than those caused by *V. vulnificus*. However, in persons with liver disease or those who are immunocompromised, fatal infections can occur. Oral antibiotics, as used for traveler's diarrhea (Chapter 265), are usually efficacious for diarrhea, although local resistance patterns vary. For skin infections, parenteral antibiotics are recommended as for *V. vulnificus* (see earlier).

279 *CAMPYLOBACTER* INFECTIONS

BAN MISHU ALLOS

DEFINITION

Campylobacter jejuni is one of the most commonly recognized bacterial causes of diarrhea in developed and underresourced nations. More than 95% of campylobacter isolated in developed countries are *C. jejuni* or *C. coli*. However, other *Campylobacter* species are also associated with human disease.

The Pathogen

Campylobacter organisms are motile, curved, gram-negative rods that are found in domestic and wild animals—especially poultry—all over the world. *C. jejuni* is microaerophilic, requires 3 to 15% oxygen for growth, and is oxidase and catalase positive. It grows best at 42° C; however, other *Campylobacter* species that may also be pathogenic grow best at 37° C. The whole genome sequences for multiple *Campylobacter* species have been determined.

EPIDEMIOLOGY

C. jejuni infections are endemic in young children in underresourced nations, where it is among the three leading causes of childhood diarrhea, along with norovirus and rotavirus (Chapter 350). In industrialized nations such as the United States, *Campylobacter* infections are the most common bacterial causes of diarrhea in children and adults, and the incidence of diagnosed *Campylobacter* infections has increased recently, likely due to the more widespread use of culture-independent diagnostic tests.[1] Nonetheless, the actual burden of disease caused by *Campylobacter* is probably much higher than suggested in surveillance reports as even active surveillance systems substantially underreport the true incidence of infection. Epidemiologic studies have estimated that more than 2 million people in the United States are infected with *C. jejuni* each year. For reasons that are not clear, the incidence is highest in western states, such as California and Hawaii. Similarly high rates of infection are observed in Europe. In the United States, Europe, and Australia, *C. jejuni* infections show a substantial peak in warmer months,[2] but such seasonality is not observed in tropical underresourced countries, perhaps because of the absence of extreme temperature variations. Polymerase chain reaction (PCR) testing and other culture-independent diagnostic tests can now identify bacterial pathogens in most individuals with traveler's diarrhea (Chapter 265), which is commonly associated with *C. jejuni*, particularly in Southeast Asia.[3]

The incidence of *Campylobacter* infections is highest in early childhood, an epidemiologic feature common to many food-borne bacterial pathogens. However, in the United States and other industrialized countries, the incidence of infections peaks again in early adulthood. The incidence of infection is also higher in men, a sex difference most pronounced in young adults.

Most human *C. jejuni* infections occur sporadically, with only a tiny fraction occurring as part of outbreaks. The dominant source of sporadic infections in both developed and underresourced countries is consumption or handling of poultry,[4] although cattle and pigs also can be sources of infection.[5] Other sources of transmission in developed nations include foreign travel, contact with pets and other animals, contaminated drinking water, and consumption of unpasteurized milk. Cross-contamination within a kitchen (e.g., use of the same utensils or cutting boards to prepare uncooked chicken and to chop fruit) has led to a variety of foods being implicated as sources of human *C. jejuni* infection. In contrast to sporadic infections, the most common source of *C. jejuni* outbreaks is unpasteurized milk; large waterborne outbreaks occasionally occur. Transmission of *C. jejuni* infection from ill food handlers is uncommon. Even in households in which an individual has culture-proven *C. jejuni* gastroenteritis, secondary transmission to other family members is unusual.

PATHOBIOLOGY

Persons become infected with *C. jejuni* as a result of orally ingesting the organism, usually in contaminated food or water. Factors that affect whether *Campylobacter* infection leads to illness include the dose of bacteria ingested, the virulence of the organism, and the specific immunity of the host to the ingested organism. The minimum number of bacteria needed to cause illness varies among people, but it may be quite low. Because *C. jejuni* is susceptible to gastric acidity, ingestion of very few organisms may cause illness if gastric pH is elevated as a result of illness or medication.

In early infection, *C. jejuni* multiplies in the bile-rich upper intestines; subsequently, tissue injury is seen in the jejunum, ileum, and colon. Gross inspection of the bowel shows a diffuse, bloody, edematous enteritis. Microscopic examination shows an inflammatory infiltrate consisting of neutrophils, mononuclear cells, and eosinophils in the lamina propria. The mucosal epithelium is ulcerated, and crypt abscesses may be seen. The pathologic appearance is nonspecific and may mimic ulcerative colitis or Crohn disease (Chapter 127).

Invasion of the epithelium by *C. jejuni* appears to be central to its pathogenesis, and many factors influence how *C. jejuni* adheres to and invades intestinal tissues. A superficial conserved antigen, PEB1, appears to be a major adhesin and is a target of the immune response to *C. jejuni* infection. Other factors contributing to the invasiveness and pathogenicity of *C. jejuni* that may be encoded by a virulence plasmid include type IV secretion systems

Nontoxigenic *Vibrio cholerae*

Nontoxigenic *V. cholerae* causes gastroenteritis, but unlike toxigenic *V. cholerae* O1 or O139, nontoxigenic *V. cholerae* does not cause epidemics. Illness ranges in severity from mild diarrhea to severe watery diarrhea. Fever and bloody diarrhea are unusual, but immunocompromised persons and those with liver disease can experience more severe illness, including fever, chills, and septic shock.

Infection with *Vibrio vulnificus*

V. vulnificus is associated with wound infections in persons in contact with contaminated water as well as with primary sepsis in immunocompromised hosts. This pathogen is responsible for 95% of seafood-related mortality in the United States. Wound infections follow trauma and are characterized by rapid progression of skin and soft tissue involvement, with necrosis and bulla formation occurring in more severe cases.[12] Fever, chills, and sepsis syndrome may ensue rapidly. Primary sepsis with bacteremia and metastatic lesions on the skin, characterized by disseminated erythematous lesions that may evolve to necrotic lesions, is a distinctive clinical manifestation in patients with chronic liver disease or alcohol dependence (Chapter 364) and in patients with blood disorders such as thalassemia (Chapter 148). Patients are acutely ill with high fever and must be managed aggressively with fluid resuscitation, surgical débridement, general supportive care, and antibiotic therapy. The recommended antibiotic therapy includes a combination of cefotaxime (2 g intravenously four times a day) plus doxycycline (100 mg orally two times a day). This combination is synergistic in vitro. Alternative antimicrobials are ceftazidime and ciprofloxacin in combination with doxycycline.

Infection with *Vibrio parahaemolyticus*

V. parahaemolyticus lives in marine environments and is a source of intestinal illness associated with the ingestion of contaminated shellfish, especially raw oysters.[13] Certain serovars have demonstrated pandemic spread (O3:K6 and O4:K68). The clinical illness may mimic cholera, but most cases are milder, with self-limited forms of acute watery diarrhea. *V. parahaemolyticus* also can cause wound infections, which are generally less severe than those caused by *V. vulnificus*. However, in persons with liver disease or those who are immunocompromised, fatal infections can occur. Oral antibiotics, as used for traveler's diarrhea (Chapter 265), are usually efficacious for diarrhea, although local resistance patterns vary. For skin infections, parenteral antibiotics are recommended as for *V. vulnificus* (see earlier).

279 *CAMPYLOBACTER* INFECTIONS

BAN MISHU ALLOS

DEFINITION

Campylobacter jejuni is one of the most commonly recognized bacterial causes of diarrhea in developed and underresourced nations. More than 95% of campylobacter isolated in developed countries are *C. jejuni* or *C. coli*. However, other *Campylobacter* species are also associated with human disease.

The Pathogen

Campylobacter organisms are motile, curved, gram-negative rods that are found in domestic and wild animals—especially poultry—all over the world. *C. jejuni* is microaerophilic, requires 3 to 15% oxygen for growth, and is oxidase and catalase positive. It grows best at 42° C; however, other *Campylobacter* species that may also be pathogenic grow best at 37° C. The whole genome sequences for multiple *Campylobacter* species have been determined.

EPIDEMIOLOGY

C. jejuni infections are endemic in young children in underresourced nations, where it is among the three leading causes of childhood diarrhea, along with norovirus and rotavirus (Chapter 350). In industrialized nations such as the United States, *Campylobacter* infections are the most common bacterial causes of diarrhea in children and adults, and the incidence of diagnosed *Campylobacter* infections has increased recently, likely due to the more widespread use of culture-independent diagnostic tests.[1] Nonetheless, the actual burden of disease caused by *Campylobacter* is probably much higher than suggested in surveillance reports as even active surveillance systems substantially underreport the true incidence of infection. Epidemiologic studies have estimated that more than 2 million people in the United States are infected with *C. jejuni* each year. For reasons that are not clear, the incidence is highest in western states, such as California and Hawaii. Similarly high rates of infection are observed in Europe. In the United States, Europe, and Australia, *C. jejuni* infections show a substantial peak in warmer months,[2] but such seasonality is not observed in tropical underresourced countries, perhaps because of the absence of extreme temperature variations. Polymerase chain reaction (PCR) testing and other culture-independent diagnostic tests can now identify bacterial pathogens in most individuals with traveler's diarrhea (Chapter 265), which is commonly associated with *C. jejuni*, particularly in Southeast Asia.[3]

The incidence of *Campylobacter* infections is highest in early childhood, an epidemiologic feature common to many food-borne bacterial pathogens. However, in the United States and other industrialized countries, the incidence of infections peaks again in early adulthood. The incidence of infection is also higher in men, a sex difference most pronounced in young adults.

Most human *C. jejuni* infections occur sporadically, with only a tiny fraction occurring as part of outbreaks. The dominant source of sporadic infections in both developed and underresourced countries is consumption or handling of poultry,[4] although cattle and pigs also can be sources of infection.[5] Other sources of transmission in developed nations include foreign travel, contact with pets and other animals, contaminated drinking water, and consumption of unpasteurized milk. Cross-contamination within a kitchen (e.g., use of the same utensils or cutting boards to prepare uncooked chicken and to chop fruit) has led to a variety of foods being implicated as sources of human *C. jejuni* infection. In contrast to sporadic infections, the most common source of *C. jejuni* outbreaks is unpasteurized milk; large waterborne outbreaks occasionally occur. Transmission of *C. jejuni* infection from ill food handlers is uncommon. Even in households in which an individual has culture-proven *C. jejuni* gastroenteritis, secondary transmission to other family members is unusual.

Other factors contributing to the invasiveness and pathogenicity of *C. jejuni* that may be encoded by a virulence plasmid include type IV secretion systems

ABSTRACT

Campylobacter organisms are small, curved, gram-negative rods that are an important cause of diarrhea in both developed and underresourced, developing nations. The most commonly encountered *Campylobacter* is *C. jejuni*, which is a leading cause of childhood diarrhea in underresourced, developing nations. In developed nations, the incidence of infection peaks again in young adulthood. Transmission to humans typically occurs from foods of animal origin, especially from poultry. An important postinfectious complication is Guillain-Barré syndrome, which complicates about 1 in 2000 *Campylobacter* infections. The gold standard for diagnosis of *Campylobacter* infection is stool culture, but culture-independent diagnostic tests are becoming more popular. The most important tenet of treatment is restoration of proper hydration and electrolyte balance. If antibiotics are needed, macrolides (azithromycin or clarithromycin) may be used.

Guillain-Barré syndrome

and mechanisms that disrupt microtubules in host cells. The presence of the plasmid pVir in clinical isolates is significantly associated with bloody stools. *C. jejuni* also may invade in an actin- and microtubule-independent manner. Glycolipids and glycoproteins on the surface of *C. jejuni* are important in the organism's survival in the intestinal lumen and in pathogenesis because they have an impact on cell-to-cell interactions as well as on the host's immune response to infection. The bacteria's flagella facilitate its ability to colonize the gastrointestinal tract by promoting the organism's motility and chemotaxis. *C. jejuni* may produce extracellular toxins, but their role in pathogenesis has not been confirmed, with the possible exception of the cytoskeletal distending toxin (CDT), which may facilitate intracellular activities that lead to apoptosis.

Regardless of the organism's virulence, host factors are pivotal in affecting the clinical outcome of infection. In healthy volunteers fed a fixed dose of a single *C. jejuni* strain, a spectrum of illnesses develops. Patients infected with *C. jejuni* excrete the organism in feces for 2 to 3 weeks. In underresourced nations, where the level of immunity to *C. jejuni* is higher because of recurrent exposure, the period of convalescent excretion of *C. jejuni* is shorter.

After recovery from *Campylobacter* infection, at least short-term immunity develops. The decreasing illness-to-infection ratio with age seen in underresourced nations also suggests that individuals are acquiring immunity. Specific immunoglobulin A, G, and M antibodies in serum and immunoglobulin A antibodies in intestinal secretions develop in patients infected with *C. jejuni*. Patients with congenital or acquired hypogammaglobulinemia are at risk for severe or recurrent *C. jejuni* infections. Because the incidence of *C. jejuni* infection is markedly higher in persons infected with human immunodeficiency virus (HIV; Chapter 358), cell-mediated immunity also plays a role in preventing and terminating infection.[6]

CLINICAL MANIFESTATIONS

The clinical consequences of *Campylobacter* infection range from complete absence of symptoms to fulminant sepsis and death. In most cases, however, illnesses are brief and do not require hospitalization. In developed nations, detection of *C. jejuni* in the stool of asymptomatic persons is rare. However, in underresourced nations, where infections are endemic and recurrent infections occur frequently, asymptomatic infections are more common. In both underresourced and developed nations, persons infected with *C. jejuni* typically contract a diarrheal illness that resolves within a week.

The gastroenteritis that is caused by infection with *C. jejuni* is clinically indistinguishable from that caused by other bacterial enteric pathogens, such as *Salmonella* (Chapter 284), *Shigella* (Chapter 285), or *Escherichia coli* O157:H7 (Chapter 280). The most common symptoms are diarrhea, malaise, fever, and abdominal pain (Table 279-1). Campylobacterosis incubation periods vary considerably, ranging from 2.5 to 4.3 days, depending on the subgroup. Most patients with *C. jejuni* gastroenteritis experience at least 1 day with 10 or more stools; the diarrhea may be loose, watery, or bloody. Older individuals are less likely to have bloody diarrhea but more likely to have symptoms severe enough to require hospitalization. Nausea is reported by some patients, but vomiting is less common. More than half the patients describe subjective fever. The abdominal cramping may be severe and is sometimes the predominant symptom. Severe abdominal pain that precedes the onset of diarrhea may mimic acute appendicitis (Chapter 128). Up to 5 kg of weight-loss may occasionally be observed.

TABLE 279-1 CLINICAL FEATURES OF *CAMPYLOBACTER* ENTERITIS DERIVED FROM OUTBREAKS IN WHICH MORE THAN 50 PATIENTS WERE INFECTED

SYMPTOM	MEDIAN FREQUENCY (%)	RANGE (%)
Fever	50	6-75
Diarrhea	84	52-100
Headache	41	6-69
Abdominal pain	79	56-99
Myalgia	42	28-59
Vomiting	15	1-42
Blood in feces	15	0.5-32

Modified from Blaser MJ, Engberg J. Clinical aspects of *Campylobacter jejuni* and *Campylobacter coli* infections. In: Nachamkin I, Szymanski CM, Blaser MJ, eds. *Campylobacter*. 3rd ed. Washington, DC: ASM Press; 2008:99-121.

Local complications of *C. jejuni* gastroenteritis are rare. In its most severe form, infection may lead to massive gastrointestinal hemorrhage or toxic megacolon. Infection of the biliary tract may result in obstructive hepatitis, cholecystitis (Chapter 141), or pancreatitis (Chapter 130). Other reported local complications include peritonitis (Chapter 128), splenic rupture, and exacerbations of inflammatory colitis. Bacteremia[7] is detected in 1.5 per 1000 intestinal infections, with higher rates in persons who are immunocompromised or elderly, but transient bacteremia may be more common because blood cultures are infrequently obtained in patients with diarrhea and the bacteria are killed rapidly by normal human serum. Other extraintestinal complications, such as meningitis, endocarditis, pericarditis, myocarditis, osteomyelitis, and purulent arthritis, are rare.

DIAGNOSIS

The diagnosis of *C. jejuni* infection should be considered in any patient with an acute febrile diarrheal illness. The diagnosis is established by culturing the organism from stool or tissue. Primary isolation of *Campylobacter* species from blood may take up to 14 days.

Culture-independent polymerase chain reaction (PCR) testing, which has a higher sensitivity[8] and is more rapidly available, is increasingly superceding culture for prompt diagnosis. Currently, however, such tests do not provide antibiotic-susceptibility data and also do not demonstrate if an isolate is part of a larger outbreak.

Almost regardless of the nature of the symptoms, fecal leukocytes are found in 75% of infected patients; gross or occult blood is seen in 50%. Peripheral white blood cell counts may be elevated, but liver function test results, the hematocrit, and serum electrolyte values are usually normal. Sigmoidoscopic examination reveals diffuse colonic inflammation, which is nonspecific.

The presence of curved gram-negative rods on a Gram stain of stool is specific but only 50 to 75% sensitive for detecting *C. jejuni*. Examination of fecal specimens by dark-field microscopy is useful if it is done within 2 hours of passage; the characteristic darting motility of *Campylobacter* provides a presumptive diagnosis. Serum serologic studies of stool are currently available only as research tools.

Differential Diagnosis

In patients with acute colitis and bloody diarrhea, especially patients whose symptoms last longer than 1 week, *Campylobacter* enteritis may be mistaken for ulcerative colitis or Crohn disease (Chapter 127). In such cases, it is critical to exclude infectious colitis before starting immunosuppressive therapy. In patients with severe abdominal pain, appendicitis may be suspected, and unnecessary appendectomy may result (Chapter 128).

TREATMENT

As is true for most patients with infectious or noninfectious diarrhea, the most important principle of treatment of *Campylobacter* gastroenteritis is restoration of proper hydration and electrolyte balance, typically with oral fluids. On occasion, intravenous fluids are needed, especially in elderly patients or young children. Most *C. jejuni* infections are self-limited and resolve without specific antibiotic treatment. Treatment with azithromycin (500 mg daily for 3 days) shortens the duration of illness by less than 48 hours. Prompt antimicrobial therapy is indicated for patients with high fever (>38.5° C), prolonged illness (>1 week), bloody stools, or worsening symptoms, as well as patients who have relapsed. Antimicrobial treatment is also warranted in the elderly, infants, pregnant women, and persons who are immunocompromised, including those infected with HIV.

Alternative antibiotics include fluoroquinolones (e.g., ciprofloxacin 750 mg orally every 12 hours for 3 days), carbapenems (e.g., meropenem 1 g IV every 8 hours for 7 days), aminoglycosides (e.g., gentamicin 3 to 5 mg/kg/day divided into three doses every 8 hours for 5 days), and clindamycin (300 mg orally every 6 hours for 5 days). However, resistance to quinolones is now common in many parts of the world.[9,10] In general, rates of resistance to ampicillin, amoxicillin, and cephalosporins are too high for them to be useful in the treatment of *C. jejuni* infections. A few case-reports have described success with use of fosfomycin (3 g orally, once).

Critically ill or septic persons with *Campylobacter* infection may benefit from carbapenems (e.g., meropenem 1 g IV every 8 hours for 7 days) or aminoglycosides (e.g., gentamicin 3 to 5 mg/kg/day divided into three doses every 8 hours for 5 days), to which campylobacters are exquisitely susceptible, with resistance rates consistently less than 1%. In contrast, persons with persistent or relapsing infection, especially those who are immunocompromised, may require prolonged use (sometimes months) of antibiotics such as a macrolide (e.g., azithromycin 500 mg orally daily) or quinolone (e.g., ciprofloxacin 750 mg orally every 12 hours). In the absence of continuing sepsis, oral agents may be used.

PREVENTION

Because the most common source of transmission of *C. jejuni* infection to humans in developed countries is by consumption and handling of poultry, interrupting this route of infection will probably have the greatest effect on reducing the burden of disease caused by *Campylobacter*. The nearly universal colonization of poultry flocks with *C. jejuni* makes eradication of the organism in chickens unlikely, but improvements in slaughtering plants appear to be reducing the level of contamination of products reaching humans. For the consumer, careful food preparation methods are critical; chicken must be cooked thoroughly. To avoid cross-contamination in the kitchen, cutting boards, knives, and other utensils used to prepare raw chicken should be washed with hot soapy water before being used to prepare foods eaten uncooked, such as fruits and vegetables. Person-to-person transmission of *Campylobacter* is not common; nevertheless, all persons with diarrhea, especially those who handle food, should wash their hands after using the bathroom. Travelers and campers should be cautioned against drinking untreated water. Many outbreaks of *C. jejuni* infection also might be avoided if persons abstain from drinking unpasteurized milk. Antibiotic prophylaxis for travelers is not advised. An effective anti-*Campylobacter* vaccine has not yet been developed.

OTHER *CAMPYLOBACTER* SPECIES

C. fetus may cause diarrhea and systemic illnesses, including meningitis,[11] in compromised hosts and diarrheal illnesses in normal hosts. Most *C. fetus* strains, unlike *C. jejuni,* are not susceptible to the lethal effect of normal human serum because they possess a protein capsule (S layer). In immunocompromised persons, *C. fetus* can cause extraintestinal illnesses such as bacteremia, vascular infections, and meningitis. *C. fetus* infection may also cause perinatal infection and fetal loss. Prolonged treatment with a macrolide (e.g., azithromycin 500 mg orally daily) plus either meropenem (1 g IV every 8 hours), an aminoglycoside (e.g., IV gentamicin, 5 mg/kg/day divided into three doses every 8 hours), or a third-generation cephalosporin (e.g., ceftriaxone 2 g IV every 24 hours) is indicated for serious *C. fetus* infections. The duration of antibiotic treatment depends upon the patient's clinical response but should be continued for 2 weeks in most cases.

C. upsaliensis may cause acute or chronic diarrhea in healthy or immunocompromised persons. The organism is frequently isolated from dogs with diarrhea, which could be a source for transmission to humans. Some *C. upsaliensis* strains are resistant to erythromycin, but most are susceptible to fluoroquinolones (e.g., ciprofloxacin 750 mg orally every 12 hours), doxycycline (100 mg orally every 12 hours for 3 days), third-generation cephalosporins (e.g., ceftriaxone 2 g IV every 24 hours for 3 to 5 days), and amoxicillin-clavulanate (875 mg orally every 12 hours for 3 to 15 days).

C. hyointestinalis was first recognized as a cause of proliferative enteritis in swine; *C. lari* is most often cultured from gulls and other birds. Both organisms have now been identified as rare causes of watery diarrhea and abdominal cramping in immunocompetent children and adults. Most infected patients do not require antimicrobial therapy; all isolates studied in vitro have been susceptible to erythromycin.

C. concisus, long believed to be part of the microbiota of healthy persons, is now considered a possible cause of human gastrointestinal illness. An increasing body of evidence also has linked *C. concisus* infection with childhood Crohn disease.

Helicobacter cinaedi and *H. fennelliae*, once called *Campylobacter*-like organisms, are causes of proctocolitis or enterocolitis and also have been reported to cause bacteremia in immunocompromised patients. Fluoroquinolones (e.g., ciprofloxacin 750 mg orally every 12 hours) are considered the treatment of choice in patients who require antimicrobial therapy. The organisms are also susceptible to third-generation cephalosporins (e.g., ceftriaxone 2 g IV every 24 hours), aminoglycosides (e.g., gentamicin 3 to 5 mg/kg/day divided into three doses every 8 hours for 5 days), and carbapenems (e.g., meropenem 1 g IV every 8 hours).

Other *Campylobacter* or related species that have been associated with human illness include *C. mucosalis, C. doylei, C. curvus, C. insulaenigrae, C. rectus, C. helveticus, Arcobacter butzleri,* and *A. cryaerophila*. Illnesses include diarrhea and localized infections, presumably as a result of transient bacteremia from intestinal sources. Recently identified *Campylobacter* species that may be clinically relevant include *C. ureolyticus, C. troglodytis, C. lari* subspecies *concheus*, and *C. peloridis*. New pathogenic species of *Campylobacter* are being identified with some regularity.

PROGNOSIS

Even in critically ill patients, 1 week of therapy is generally sufficient to eradicate infection. Although the symptoms resolve within 7 days in most patients, symptoms may persist in 10 to 20% of patients, and another 5 to 10% may experience a relapse. The case-fatality rate associated with *Campylobacter* infection is low, about 0.05 death per 1000 infections, but not surprisingly is highest among the elderly and persons with comorbid conditions.

Campylobacter infections in HIV-positive patients may be more severe, persist, recur, and be antibiotic resistant. More severe and extraintestinal illness is also more likely to occur in patients with acquired or congenital hypogammaglobulinemia. Most *C. jejuni* gastrointestinal infections in pregnant women are mild and self-limited, with no severe consequences for the mother or baby. However, if bacteremia develops in the mother, placental infection and fetal death may ensue. Infection during the third trimester can also cause neonatal sepsis and death if the woman is excreting *Campylobacter* in her stool at the time of delivery.

Guillain-Barré syndrome (Chapter 388), which is a postinfectious complication of *C. jejuni* infection, occurs about once in every 2000 infections; between 30 and 50% of all cases of Guillain-Barré syndrome may be triggered by a preceding *C. jejuni* infection.[12–14] Because the onset of neurologic symptoms occurs about 1 to 3 weeks after the onset of gastrointestinal symptoms, cross-reactivity between antibodies formed against the lipopolysaccharide and capsule of *C. jejuni* and proteins in peripheral nerve myelin or other glycolipids in peripheral nerves is probably the cause. Certain *C. jejuni* serotypes (O type 19, O type 41) are overrepresented in patients in whom Guillain-Barré syndrome develops after culture-documented *C. jejuni* infection. Other postinfectious complications of *C. jejuni* infection include reactive arthritis (seen mostly in persons with HLA-B27 histocompatibility antigens; Chapter 254), uveitis (Chapter 391), hemolytic-uremic syndrome (Chapter 158), erythema nodosum (Fig. 407-24 and Table 403-3), encephalitis (Chapter 383), myocarditis (Chapter 47), hemolytic anemia, and chronic gastrointestinal consequences such as irritable bowel syndrome[15] (Chapter 123), inflammatory bowel disease (Chapter 127), and celiac disease (Chapter 126).

280 *ESCHERICHIA COLI* ENTERIC INFECTIONS

THEODORE S. STEINER

DEFINITION

Bacteria belonging to the species *Escherichia coli* are a normal component of the intestinal microbiota (Chapter 257). The majority of *E. coli* are harmless commensals, but specific isolates have acquired pathogenicity genes that enable them to cause diseases, including urinary tract infections, bacteremia, meningitis, and diarrheal illness. One particular challenge to the clinician and microbiology laboratory is how to distinguish these pathogenic *E. coli* from harmless commensal strains so as to better guide diagnosis and treatment.

Virulence traits include a variety of toxins, adherence factors, and secreted mediators that work together to perturb the host's intestinal physiology. Specific combinations of these factors produce six major pathotypes of diarrheagenic *E. coli*: enterotoxigenic, enteroinvasive, enterohemorrhagic, enteropathogenic, enteroaggregative, and diffusely adherent. In addition, these pathotypes frequently overlap, thereby leading to "hybrid" or "heteropathogenic" strains. Atypical strains also may carry partial genetic signatures of one or a combination of pathotypes. For example, *E. coli* that express Shiga-like toxins characteristic of enterohemorrhagic *E. coli* without the usual associated adherence factors are now collectively known as shigatoxigenic *E. coli*. Strains that carry more virulence genes are more strongly associated with diarrhea.

The Pathogen

E. coli is a small catalase-positive, oxidase-negative, gram-negative bacillus in the family Enterobacteriaceae. *E. coli* is the predominant member of the

PREVENTION

Because the most common source of transmission of *C. jejuni* infection to humans in developed countries is by consumption and handling of poultry, interrupting this route of infection will probably have the greatest effect on reducing the burden of disease caused by *Campylobacter*. The nearly universal colonization of poultry flocks with *C. jejuni* makes eradication of the organism in chickens unlikely, but improvements in slaughtering plants appear to be reducing the level of contamination of products reaching humans. For the consumer, careful food preparation methods are critical; chicken must be cooked thoroughly. To avoid cross-contamination in the kitchen, cutting boards, knives, and other utensils used to prepare raw chicken should be washed with hot soapy water before being used to prepare foods eaten uncooked, such as fruits and vegetables. Person-to-person transmission of *Campylobacter* is not common; nevertheless, all persons with diarrhea, especially those who handle food, should wash their hands after using the bathroom. Travelers and campers should be cautioned against drinking untreated water. Many outbreaks of *C. jejuni* infection also might be avoided if persons abstain from drinking unpasteurized milk. Antibiotic prophylaxis for travelers is not advised. An effective anti-*Campylobacter* vaccine has not yet been developed.

OTHER *CAMPYLOBACTER* SPECIES

C. fetus may cause diarrhea and systemic illnesses, including meningitis,[11] in compromised hosts and diarrheal illnesses in normal hosts. Most *C. fetus* strains, unlike *C. jejuni,* are not susceptible to the lethal effect of normal human serum because they possess a protein capsule (S layer). In immunocompromised persons, *C. fetus* can cause extraintestinal illnesses such as bacteremia, vascular infections, and meningitis. *C. fetus* infection may also cause perinatal infection and fetal loss. Prolonged treatment with a macrolide (e.g., azithromycin 500 mg orally daily) plus either meropenem (1 g IV every 8 hours), an aminoglycoside (e.g., IV gentamicin, 5 mg/kg/day divided into three doses every 8 hours), or a third-generation cephalosporin (e.g., ceftriaxone 2 g IV every 24 hours) is indicated for serious *C. fetus* infections. The duration of antibiotic treatment depends upon the patient's clinical response but should be continued for 2 weeks in most cases.

C. upsaliensis may cause acute or chronic diarrhea in healthy or immunocompromised persons. The organism is frequently isolated from dogs with diarrhea, which could be a source for transmission to humans. Some *C. upsaliensis* strains are resistant to erythromycin, but most are susceptible to fluoroquinolones (e.g., ciprofloxacin 750 mg orally every 12 hours), doxycycline (100 mg orally every 12 hours for 3 days), third-generation cephalosporins (e.g., ceftriaxone 2 g IV every 24 hours for 3 to 5 days), and amoxicillin-clavulanate (875 mg orally every 12 hours for 3 to 15 days).

C. hyointestinalis was first recognized as a cause of proliferative enteritis in swine; *C. lari* is most often cultured from gulls and other birds. Both organisms have now been identified as rare causes of watery diarrhea and abdominal cramping in immunocompetent children and adults. Most infected patients do not require antimicrobial therapy; all isolates studied in vitro have been susceptible to erythromycin.

C. concisus, long believed to be part of the microbiota of healthy persons, is now considered a possible cause of human gastrointestinal illness. An increasing body of evidence also has linked *C. concisus* infection with childhood Crohn disease.

Helicobacter cinaedi and *H. fennelliae*, once called *Campylobacter*-like organisms, are causes of proctocolitis or enterocolitis and also have been reported to cause bacteremia in immunocompromised patients. Fluoroquinolones (e.g., ciprofloxacin 750 mg orally every 12 hours) are considered the treatment of choice in patients who require antimicrobial therapy. The organisms are also susceptible to third-generation cephalosporins (e.g., ceftriaxone 2 g IV every 24 hours), aminoglycosides (e.g., gentamicin 3 to 5 mg/kg/day divided into three doses every 8 hours for 5 days), and carbapenems (e.g., meropenem 1 g IV every 8 hours).

Other *Campylobacter* or related species that have been associated with human illness include *C. mucosalis, C. doylei, C. curvus, C. insulaenigrae, C. rectus, C. helveticus, Arcobacter butzleri,* and *A. cryaerophila*. Illnesses include diarrhea and localized infections, presumably as a result of transient bacteremia from intestinal sources. Recently identified *Campylobacter* species that may be clinically relevant include *C. ureolyticus, C. troglodytis, C. lari* subspecies *concheus*, and *C. peloridis*. New pathogenic species of *Campylobacter* are being identified with some regularity.

PROGNOSIS

Even in critically ill patients, 1 week of therapy is generally sufficient to eradicate infection. Although the symptoms resolve within 7 days in most patients, symptoms may persist in 10 to 20% of patients, and another 5 to 10% may experience a relapse. The case-fatality rate associated with *Campylobacter* infection is low, about 0.05 death per 1000 infections, but not surprisingly is highest among the elderly and persons with comorbid conditions.

Campylobacter infections in HIV-positive patients may be more severe, persist, recur, and be antibiotic resistant. More severe and extraintestinal illness is also more likely to occur in patients with acquired or congenital hypogammaglobulinemia. Most *C. jejuni* gastrointestinal infections in pregnant women are mild and self-limited, with no severe consequences for the mother or baby. However, if bacteremia develops in the mother, placental infection and fetal death may ensue. Infection during the third trimester can also cause neonatal sepsis and death if the woman is excreting *Campylobacter* in her stool at the time of delivery.

Guillain-Barré syndrome (Chapter 388), which is a postinfectious complication of *C. jejuni* infection, occurs about once in every 2000 infections; between 30 and 50% of all cases of Guillain-Barré syndrome may be triggered by a preceding *C. jejuni* infection.[12–14] Because the onset of neurologic symptoms occurs about 1 to 3 weeks after the onset of gastrointestinal symptoms, cross-reactivity between antibodies formed against the lipopolysaccharide and capsule of *C. jejuni* and proteins in peripheral nerve myelin or other glycolipids in peripheral nerves is probably the cause. Certain *C. jejuni* serotypes (O type 19, O type 41) are overrepresented in patients in whom Guillain-Barré syndrome develops after culture-documented *C. jejuni* infection. Other postinfectious complications of *C. jejuni* infection include reactive arthritis (seen mostly in persons with HLA-B27 histocompatibility antigens; Chapter 254), uveitis (Chapter 391), hemolytic-uremic syndrome (Chapter 158), erythema nodosum (Fig. 407-24 and Table 403-3), encephalitis (Chapter 383), myocarditis (Chapter 47), hemolytic anemia, and chronic gastrointestinal consequences such as irritable bowel syndrome[15] (Chapter 123), inflammatory bowel disease (Chapter 127), and celiac disease (Chapter 126).

280 *ESCHERICHIA COLI* ENTERIC INFECTIONS

THEODORE S. STEINER

DEFINITION

Bacteria belonging to the species *Escherichia coli* are a normal component of the intestinal microbiota (Chapter 257). The majority of *E. coli* are harmless commensals, but specific isolates have acquired pathogenicity genes that enable them to cause diseases, including urinary tract infections, bacteremia, meningitis, and diarrheal illness. One particular challenge to the clinician and microbiology laboratory is how to distinguish these pathogenic *E. coli* from harmless commensal strains so as to better guide diagnosis and treatment.

Virulence traits include a variety of toxins, adherence factors, and secreted mediators that work together to perturb the host's intestinal physiology. Specific combinations of these factors produce six major pathotypes of diarrheagenic *E. coli*: enterotoxigenic, enteroinvasive, enterohemorrhagic, enteropathogenic, enteroaggregative, and diffusely adherent. In addition, these pathotypes frequently overlap, thereby leading to "hybrid" or "heteropathogenic" strains. Atypical strains also may carry partial genetic signatures of one or a combination of pathotypes. For example, *E. coli* that express Shiga-like toxins characteristic of enterohemorrhagic *E. coli* without the usual associated adherence factors are now collectively known as shigatoxigenic *E. coli*. Strains that carry more virulence genes are more strongly associated with diarrhea.

The Pathogen

E. coli is a small catalase-positive, oxidase-negative, gram-negative bacillus in the family Enterobacteriaceae. *E. coli* is the predominant member of the

ABSTRACT

Diarrheagenic *Escherichia coli* refers to a group of "pathotypes" of bacteria capable of adhering to intestinal epithelia and perturbing their function so as to cause illness. Each of six recognized pathotypes of diarrheagenic *E. coli* have distinct yet frequently overlapping epidemiologic and clinical features. Enteropathogenic *E. coli* cause infantile diarrhea in developing areas. Enterotoxigenic and enteroaggregative *E. coli* are the major causes of diarrhea in travelers to developing areas and, along with diffusely adherent *E. coli*, also cause endemic childhood diarrhea. Enterohemorrhagic *E. coli* cause sporadic and outbreak-associated hemorrhagic colitis, as well as hemolytic-uremic syndrome. Enteroinvasive *E. coli* cause a *Shigella*-like inflammatory enterocolitis. Although diarrheagenic *E. coli* infections are usually self-limited, they can lead to important complications and considerable morbidity or even mortality.

E. coli
traveler's diarrhea
hemorrhagic colitis
hemolytic-uremic syndrome
Shiga-like toxins

Gammaproteobacteria in the intestinal tract of humans and other mammals, although it is greatly outnumbered by members of other bacterial phyla, which largely consist of strict anaerobes.

E. coli possess a complex envelope that consists of a plasma membrane, a peptidoglycan cell wall, and an outer membrane. The microorganism's outer membrane confers mechanical properties of stiffness and strength. The lipopolysaccharide cell wall of *E. coli* contains immunostimulatory lipid A attached to a core oligosaccharide chain. Most *E. coli* have immunogenic carbohydrate chains, known as O antigens, attached to this core glycolipid to produce over 170 O serogroups. *E. coli* also have at least 56 distinct flagellar (H) antigens based on variable domains of the flagellin gene. Some 80 variably heat-labile capsular (K) antigens have also been described.

E. coli are major components of the normal gut microbiota, but diarrheagenic *E. coli* differ from these commensals in their specific abilities to cause clinically meaningful infection in the gut. These pathogens seldom spread systemically, but they share virulence traits with extraintestinal pathogenic *E. coli* and uropathogenic *E. coli*, although these latter organisms are typically hybrid strains as opposed to classic diarrheagenic strains. Numerous adherence, enterotoxic, cytotoxic, and invasiveness factors may be gained or lost by a particular serotype because they are characteristically encoded on transmissible genetic elements such as plasmids or bacteriophages. These factors convey the pathotype of disease because they allow colonization and perturbation of host intestinal physiology. Molecular analysis shows that commensal and pathogenic *E. coli* cluster into phylogenetic groups that are independent of O:H serotype.[1] Moreover, the *E. coli* taxon now also includes *Shigella*, based on genomic identity, although the latter can still be distinguished biochemically. Nevertheless, relatively few O serogroups tend to predominate in the normal human colon (O groups 1, 2, 4, 6, 7, 8, 18, 25, 45, 75, and 81), whereas others tend to be associated with specific virulence traits and thus different types of pathogenesis in the intestine.

EPIDEMIOLOGY

Enteric *E. coli* infections are acquired by the fecal-oral route, although the fecal sources and infectivity differ among the pathotypes. From the host perspective, the most important risk factors for illness due to diarrheagenic *E. coli* include young age and residence in or travel to low-income areas of the world where water purification is challenging. Nevertheless, *E. coli* is among the leading causes of hospitalization for acute gastroenteritis in the United States along with norovirus (Chapter 350) and Salmonella (Chapter 284).[2] Other host risk factors for diarrheogenic *E. coli* infection include recent use of antibiotics and loss of gastric acid. In addition, specific single-nucleotide polymorphisms in several human genes encoding inflammatory mediators are associated with traveler's diarrhea caused by enterotoxigenic *E. coli*, enteroaggregative *E. coli*, or both.[3] Interestingly, nonenteric travel-acquired *E. coli* strains rarely cause clinical disease.[4]

The advent of molecular diagnostics has expanded the understanding of diarrheagenic *E. coli* by identifying specific genes that characterize individual pathotypes. This information can be useful for an individual patient as well as for studying outbreaks of diarrhea.

Enteropathogenic and Enterotoxigenic Strains

A human reservoir is probably required for most recognized types of enteropathogenic *E. coli* and enterotoxigenic *E. coli*, but domestic dogs and cats can also harbor human pathogenic strains. The infectious dose of enterotoxigenic *E. coli* in volunteers is 10^6 to 10^{10} organisms, thereby indicating that the organism usually must multiply in contaminated food or water for its effective transmission and that spread directly from person to person is unusual, except in rare outbreaks in newborn nurseries. Heavy contamination with enterotoxigenic *E. coli* has been documented in foods prepared in homes, restaurants, and by street vendors, as well as in drinking water in many tropical areas. Contaminated water and food represent the major sources of human enterotoxigenic *E. coli* infection, primarily in warm or wet seasons.

As with most diarrheal illnesses, the highest age-specific attack rates of enterotoxigenic *E. coli* are found in young children, in whom enterotoxigenic *E. coli* account for anywhere from 3 to 39% (average, 13%) of acute diarrheal illnesses. As for immunologically inexperienced young children, a traveler visiting tropical areas has a 30 to 50% chance of acquiring traveler's diarrhea (Chapters 262 and 265) during a 2- to 3-week stay unless they avoid untreated water or ice and uncooked foods such as salads. The most commonly identified pathogen associated with diarrhea in most studies of travelers to tropical areas of the world is enterotoxigenic *E. coli*. A close second is enteroaggregative *E. coli*.

Typical enteropathogenic *E. coli* strains have been recognized primarily in poor urban areas. "Atypical" enteropathogenic *E. coli* strains, which possess the locus of enterocyte effacement but not the bundle-forming pilus gene, predominate in developed areas but can be found in developing areas as well.[5] Enteropathogenic strains remain a common pathogen, and "typical" enteropathogenic *E. coli* are still generally associated with diarrhea rather than asymptomatic colonization.

Enteroaggregative Strains

The natural reservoir of enteroaggregative *E. coli* is not known, but outbreaks have been traced to contaminated food, and live organisms can be found in drinking water, table salsa, and other consumable items in endemic tropical areas. A high infectious dose is required for acquisition, but person-to-person transmission can occur among men who have sex with men.[6] In addition to its role in traveler's diarrhea, enteroaggregative *E. coli* is an important cause of both acute and persistent diarrhea, as well as malnutrition (Chapter 197), especially in children in tropical areas and in patients with HIV/AIDS (Chapter 358). It also is a major cause of sporadic diarrhea in the United States, Europe, China, and other developed areas.

Diffusely Adherent Strains

Diffusely adherent *E. coli* remain the least well-understood pathotype and have not consistently been found more often in patients with diarrhea than in controls, except for acute diarrhea in children in developing areas. Part of the difficulty is the heterogeneity of strains, some of which express different types of adhesins and different groups of virulence traits, thereby leading to inconsistent pathogenicity.

Enterohemorrhagic Strains

Enterohemorrhagic *E. coli* frequently colonize commercial livestock but do not infect them. Enterohemorrhagic *E. coli* (O157:H7 and others) infections can be caused by undercooked hamburgers, but large outbreaks have also been associated with contamination of the domestic water supply, unpasteurized apple juice, spinach, seed sprouts, flour,[7] and other vegetable items.

Unlike enterotoxigenic strains, transmission requires only a low infectious dose of enterohemorrhagic *E. coli* O157:H7, so person-to-person spread can lead to secondary cases. Secondary cases of shigatoxigenic/enteroaggregative *E. coli* O104:H4 may have occured but appear to be very rare. Enterohemorrhagic *E. coli* and shigatoxigenic *E. coli* infections are especially alarming because of the risk of hemolytic-uremic syndrome (Chapter 158).

Enteroinvasive Strains

Limited data on enteroinvasive *E. coli* suggest that infectious doses are relatively high, but adequate numbers of organisms can readily be spread in food with high attack rates in outbreak situations. This characteristic distinguishes enteroinvasive *E. coli* epidemiologically from *Shigella* (Chapter 285), which is easily spread person-to-person as well as by contaminated food and water.

PATHOBIOLOGY

Enteric infections caused by *E. coli* may involve the small intestine, colon, or both, depending on the organism's genetic codes for virulence traits. Well-established mechanisms of pathogenesis of *E. coli* enteric diseases include secretion of enterotoxins (enterotoxigenic *E. coli*), tissue invasion leading to cell death (*Shigella* and enteroinvasive *E. coli*), and epithelial necrosis when Shiga-like toxins (Stx1/Stx2) cause food-borne hemorrhagic colitis (enterohemorrhagic *E. coli* and shigatoxigenic *E. coli*) (see Table 280-1). By comparison, the classically recognized enteropathogenic *E. coli* are neither enterotoxigenic per se nor invasive, but rather use a specialized apparatus called a type III secretion system to inject protein "effectors" directly into host cells, thereby allowing them to attach to and efface the epithelium and leading to formation of epithelial pedestals with intimately adherent bacteria. Specific gene clusters and increasing copy numbers of the locus of enterocyte effacement *eae* gene may characterize diarrheagenic strains compared with nonpathogenic colonizers.[8] Still other types of diarrheagenic *E. coli* can also exhibit aggregating (enteroaggregative *E. coli*) or diffuse adherence (diffusely adherent *E. coli*) to epithelial cells.

The pathogenesis of enteric *E. coli* infection begins with ingestion of the organism. It then faces the normal gastric acid barrier. Both enterotoxigenic *E. coli* and enteroinvasive *E. coli* appear to be sensitive to gastric acid, which increases the infectious dose by 100- to 1000-fold. Even though enterohemorrhagic *E. coli* expresses acid tolerance factors that may facilitate its survival in the stomach, hypochlorhydria is a risk factor for hemolytic-uremic syndrome. After ingestion and passage through the stomach, enteric *E. coli* colonize the

TABLE 280-1 DIFFERENT TYPES OF ENTERIC *ESCHERICHIA COLI* INFECTIONS

TYPE	MECHANISM	DETECTION	CLINICAL SYNDROMES
ENTEROPATHOGENIC *E. COLI*			
Typical enteropathogenic	Attach then efface the mucosa by injecting virulence factors via the type III secretion system	Gene probe or PCR for *eae* and *bfpA;* serotype, focal HeLa cell adhesion, pedestal formation	Infantile diarrhea in developing areas
Atypical enteropathogenic	Attach and efface but different microcolony formation	Gene probe or PCR for *eae*; cell adherence (variable)	Infantile and animal diarrhea in developed areas
ENTEROTOXIGENIC *E. COLI*			
Heat-labile toxin (LT) Heat-stable toxin (STa: STh or STp)	Activates intestinal adenylate cyclase Activates intestinal guanylate cyclase	Gene probe, PCR for LT PCR; EIA, suckling mice, 6-hour ileal loop assay, gene probes	Watery diarrhea, traveler's diarrhea Watery diarrhea, traveler's diarrhea
ENTEROAGGREGATIVE *E. COLI*			
	Colonize in aggregates by unique fimbriae; SPATE toxins, mucinase, biofilm, type VI secretion system	PCR for *aggR* and *aatA*; aggregative adherence to cells or strata; AA gene probe; biofilm formation	Endemic persistent diarrhea, acute traveler's diarrhea, sporadic acute diarrhea
DIFFUSELY ADHERENT *E. COLI*			
	Colonize (e.g., F1845 afimbriate adhesin); SPATE toxins, and type III secretion system in some isolates	Gene probe/PCR; HeLa cell adherence	Persistent diarrhea in children >18 months old
SHIGATOXIGENIC *E. COLI*			
Enterohemorrhagic	Shiga-like toxins and attaching/effacing ability via type III secretion system	PCR or EIA for Stx1/2, serotype, cell adhesion with pedestal formation; Vero cell cytotoxicity; sorbitol agar; PCR for *eae*	Hemorrhagic colitis (afebrile, bloody diarrhea); HUS in some cases
Non-enterohemorrhagic	Shiga-like toxins, only without attaching/effacing; may carry other virulence phenotypes	PCR or Stx EIA; negative for *eae*	Hemorrhagic colitis, HUS, or benign watery diarrhea
ENTEROINVASIVE *E. COLI*			
	Cell invasion and spread	PCR for *ipaH;* Sereny test, gene probe	Inflammatory dysentery

AA = aggregative adherence; EIA = enzyme immunoassay; HUS = hemolytic-uremic syndrome; LT = heat-labile; PCR = polymerase chain reaction; SPATE = serine protease autotransporter of Enterobacteriaceae.

involved part of the intestinal tract using specialized adhesins and the coordinated expression of virulence traits. The result is the production of toxins, intracellular invasion, or other disruptions of host cell physiology.

Enteropathogenic *E. coli*

Typical enteropathogenic *E. coli* strains express plasmid-encoded genes that confer localized adherence to epithelial cells (through specialized bundle-forming pili) and chromosomal genes that mediate attachment and effacement of microvilli. The latter is characterized by the formation of cellular pedestals that hold the bacteria intimately to the cell surface. These changes in the host epithelia are mediated by protein effectors injected directly into host cells by a specialized type III secretion system encoded on the chromosomal locus of enterocyte effacement. These secreted effectors cause cellular changes that lead to villous atrophy, mucosal thinning, inflammation in the lamina propria, and variable hyperplasia of crypt cells. These morphologic changes are associated with a reduction in mucosal brush border enzymes and may contribute to the impaired absorptive function and diarrhea. Atypical enteropathogenic *E. coli* strains are generally defined as strains that express the locus of enterocyte effacement but not the bundle-forming pili; they maintain the ability to attach/efface and cause epithelial injury.

Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* colonizes the upper portion of the small bowel using fimbriate or fibrillar surface proteins known as colonization factor antigens. These proteins bind the organism to cell surface receptors on enterocytes. Whereas this colonization itself can lead to mild inflammatory changes in the epithelium, the majority of enterotoxigenic *E. coli* illness is caused by its enterotoxins. Heat-labile toxin, with a molecular weight of about 86,000, consists of five binding "B" subunits and an enzymatic "A" subunit, and, like the closely related choleratoxin (Chapter 278), binds to a monosialoganglioside receptor. Also like choleratoxin, the A subunit is an enzyme that ADP-ribosylates the regulatory subunit of adenylate cyclase, thereby leading to constitutive production of cyclic adenosine monophosphate. The consequently increased chloride secretion and reduced sodium absorption combine to cause net isotonic electrolyte loss that can be as great as 1 liter/hour. Other human enterotoxigenic *E. coli* strains produce a heat-stable toxin, which is a much smaller peptide than heat-labile toxin (18 to 19 amino acids) and which activates intestinal particulate guanylate cyclase. Like cyclic adenosine monophosphate, the cyclic guanosine monophosphate thus formed also causes net secretion. Both the colonization traits and production of enterotoxin are encoded on transmissible plasmids. Besides the complications of dehydration, the only significant pathologic change with enterotoxigenic *E. coli* is depletion of mucus from intestinal goblet cells.

Enteroaggregative *E. coli*

Enteroaggregative *E. coli* is defined by a characteristic aggregative adherence pattern to cells and the substrata associated with the formation of biofilm. This adherence requires a large plasmid known as the AA plasmid, which encodes specialized aggregative adherence fimbriae and other virulence genes, including a serine protease autotransporter toxin known as Pet and an antiaggregative protein called dispersin. Chromosomal virulence traits include a mucinase (Pic) and additional enterotoxins, as well as type VI secretion systems. Data suggest that the organisms do not intimately adhere or invade but rather reside within a biofilm at the epithelial surface, where secreted factors contribute to a damaging host inflammatory response.

Diffusely Adherent *E. coli*

The fundamental pathogenesis of diffusely adherent *E. coli* appears to depend on direct interactions between specialized adhesins (Afa/Dr) and host membrane proteins such as CD55 (decay-accelerating factor) or carcinoembryonic antigen. Many diffusely adherent *E. coli* strains are closely related to uropathogenic *E. coli* with similar virulence traits. Some strains also express other virulence factors, including serine protease autotransporter toxins, such as Sat and EspP, and a type III secretion system.[9]

Enterohemorragic *E. coli*

Enterohemorrhagic *E. coli*, most notably serotype O157:H7 (but also serogroups O26, O39, and others), cause type III secretion-dependent intimate adherence and microvillous effacement like enteropathogenic *E. coli*, but they also produce Shiga-like toxins that are responsible for the characteristic colonic mucosal disruption and hemorrhage as well as the complication of hemolytic-uremic syndrome. These toxins bind to the Gb3 surface ganglioside, thereby leading to internalization and enzymatic inactivation of ribosomes and a halting of protein synthesis. The high expression of Gb3 on vascular endothelial cells in the colon, kidney, and brain may explain the predilection for hemolytic-uremic syndrome to affect these organs. Organisms that produce

Shiga-like toxins without intimate adherence and pedestal formation are known as shigatoxigenic *E. coli* or verotoxigenic *E. coli*, and they often lack the other virulence traits necessary for colonization and disease production. The terms enterohemorrhagic *E. coli*, shigatoxigenic *E. coli*, and verotoxigenic *E. coli* were often used interchangeably until the important role of the attaching/effacing ability of true enterohemorrhagic *E. coli* strains like O157:H7 was understood.[10]

Enteroinvasive *E. Coli*

Enteroinvasive *E. coli*, like the closely related *Shigella* (Chapter 285), can invade and multiply in epithelial cells, cause experimental conjunctivitis in guinea pigs (known as the Sereny test), and produce inflammatory colitis and dysenteric, or bloody, diarrhea. As with shigellosis, a striking inflammatory response occurs, with numerous polymorphonuclear leukocytes in stool. The colon shows patchy, acute mucosal and submucosal inflammation with focal denuding of the surface epithelium, usually without deeper invasion or systemic spread. The epithelial cell invasiveness of both enteroinvasive *E. coli* and *Shigella* is encoded on a large 120- to 140-Md plasmid, which some pathogenic strains have independently acquired.

CLINICAL MANIFESTATIONS

The clinical manifestations of enteric *E. coli* infections differ among the pathotypes. For example, the incubation period averages 14 hours for enteroaggregative *E. coli*, 2 days for enterotoxigenic *E. coli*, 3 to 4 days for enterohemorrhagic *E. coli* O157:H7, but 8 days for shigatoxigenic/enteroaggregative *E. coli* O104:H4.

Enteropathogenic *E. coli*

Outbreaks of enteropathogenic *E. coli* infection in newborn nurseries have ranged from mild transient diarrhea to severe and rapidly fatal diarrheal illnesses, especially in premature or otherwise compromised infants. Diarrheal illness also can affect adults but does not have any specific distinguishing features.

Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* infections generally produce watery diarrhea, particularly in young children and travelers to tropical or developing areas. Diarrhea may range from mild to very severe, and it may be life-threatening, especially in small children and elderly individuals, who are particularly prone to dehydration, undernutrition, and electrolyte imbalance (especially hypokalemia and acidosis). Other characteristic symptoms include malaise, abdominal cramping, anorexia, and occasionally nausea, vomiting, or low-grade fever. The illness is generally self-limited to 1 to 5 days and rarely extends beyond 10 to 14 days. However, the mucosal absorptive capacity may be impaired for up to 3 weeks. Infections with enterotoxigenic *E. coli* that produce both heat-stable toxin and heat-labile toxin or heat-stable toxin alone may be more severe than those caused by enterotoxigenic *E. coli* that produce only heat-labile toxin.

Enteroaggregative *E. coli*

Enteroaggregative *E. coli* has been associated with persistent diarrhea and malnutrition (Chapter 197) in children in developing areas, in patients with HIV/AIDS (Chapter 358), and in travelers (Chapter 265) who experience diarrhea (especially those genetically predisposed to greater inflammatory responses). Although infection is frequently asymptomatic, it may cause subclinical inflammation and lead to growth shortfalls. No characteristic clinical features of enteroaggregative *E. coli* have been consistently identified, although some outbreaks have been associated with bloody diarrhea and elevated inflammatory markers in stool. The median duration of illness tends to be longer than for other diarrheagenic *E. coli* pathotypes, even as long as 14 days.[11]

Diffusely Adherent *E. coli*

Diffusely adherent *E. coli* has been associated with diarrhea with no particular identifying features, largely in children older than 18 months. Strains that are associated with diarrhea also are likely to induce inflammation.[12]

Enterohemorrhagic *E. coli*

Hemorrhagic colitis associated with enterohemorrhagic *E. coli* classically begins with watery diarrhea that quickly turns grossly bloody, with a conspicuous absence of fever or inflammatory exudate in stool but with significant abdominal pain. Although this diarrheal illness is self-limited, potentially fatal hemolytic-uremic syndrome (Chapter 158) or thrombotic thrombocytopenic purpura (Chapter 158) subsequently develops in a significant number of children and older adults (Chapter 158). Outbreaks of hemorrhagic colitis secondary to enterohemorrhagic *E. coli* in nursing homes or other institutions may be common and severe. The illness is characteristically self-limited to 5 to 12 days (mean, 7.8 days). The clinical manifestations of the heat-stable toxin/enteroaggregative *E. coli* O104:H4 are similar, although rates of hemolytic-uremic syndrome (Chapter 158) are significantly higher (more than 20%), and women are disproportionately affected.

Enteroinvasive *E. coli*

Infection with enteroinvasive *E. coli* is characterized by inflammatory colitis, often with abdominal pain, high fever, tenesmus, and bloody or dysenteric diarrhea, essentially like that seen with *Shigella* (Chapter 285). The duration of diarrhea is generally self-limited to 7 to 10 days.

DIAGNOSIS

Definitive diagnosis of *E. coli* diarrhea requires documentation of the specific virulence trait or serotype, now almost always by polymerase chain reaction (PCR) or similar molecular testing of diarrheal stool.[13] PCR testing can also be used to test a suspected food or water source.[14] The identification of subtypes of *E. coli* is clinically important during outbreaks or when shigatoxigenic *E. coli* is suspected, such as in any patient who has visible blood in any stool sample.

Differential Diagnosis

Numerous other causes of diarrhea must be considered, depending on the clinical circumstances (Chapters 126 and 265). For example, self-limited, noninflammatory diarrhea in tropical, developing areas is most likely due to enterotoxigenic *E. coli*, enteroaggregative *E. coli*, rotaviruses (young children), or noroviruses (older children and adults) (Chapter 350). Noninflammatory diarrhea in older children or adults in temperate areas is more likely to be due to noroviruses (Chapter 350). *Vibrio* infections (Chapter 278) are common in areas endemic for cholera or in any coastal area where inadequately cooked seafood is frequently eaten. If diarrhea persists beyond a week, especially with weight loss, other possibilities include *Clostridioides difficile* (Chapter 271), *Giardia lamblia* (Chapter 322), *Cryptosporidium* (Chapter 320), *Cyclospora* (Chapter 324), and microsporidial infection (Chapter 324). In outbreaks of acute food poisoning, *Staphylococcus aureus* (Chapter 267), *Clostridium perfringens* (Chapter 271), and *Bacillus cereus* should be considered.

Inflammatory colitis with high fever and tenesmus as well as leukocytes, mucus, and blood in the stool may well be due to enteroinvasive *E. coli* but should prompt a stool culture for more common invasive pathogens, such as *Campylobacter jejuni* (Chapter 279), *Shigella* (Chapter 285), *Salmonella* (Chapter 284), *Yersinia enterocolitica* (Chapter 288), or noncholera *Vibrio* (Chapter 278). Inflammatory bowel disease (Chapter 127) can also present acutely as an inflammatory diarrhea and should be considered in cases where symptoms persist and no pathogen is identified. Any patient with diarrhea and a history of recent antibiotic use, gastrointestinal surgery, or parturition should be screened for toxigenic *Clostridioides difficile* (Chapter 271).

In patients with bloody diarrhea, enterohemorrhagic *E. coli* should be strongly considered, particularly in the absence of fever. It is recommended that laboratories now routinely screen for this pathogen in all stool cultures, but especially in grossly bloody samples. Ischemic colitis (Chapter 129) and cytomegalovirus colitis (Chapter 347) can mimic enterohemorrhagic *E. coli* but typically occur only in people at risk (vascular disease and immune compromise or inflammatory bowel disease, respectively).

TREATMENT

Hydration

As with all diarrheal illnesses, the primary treatment for most *E. coli* diarrhea is replacement and maintenance of water and electrolytes, usually with a simple oral rehydration solution that uses the intact, sodium-coupled glucose or amino acid absorption (or both) to replace the fluid losses. Oral rehydration solution should be given ad libitum with free water. In breast-fed infants, continued breast-feeding and early refeeding can compensate for the nutritional losses without an adverse effect on diarrhea output. Zinc supplementation is also recommended for diarrhea in children older than 6 months in developing areas where zinc deficiency is common because it significantly reduces diarrhea volume.

Symptomatic Treatment

Antimotility agents (e.g., loperamide [2 to 4 mg as a single dose, followed by 2 mg after each loose stool up at a maximum of 16 mg/day in adults]) reduce the frequency of diarrheal stools but should not be used when fever or bloody diarrhea is present because they can increase the risk of mortality due to toxic megacolon or hemolytic-uremic syndrome. Bismuth subsalicylate (262 to

524 mg up to four times a day) may reduce symptoms in traveler's diarrhea (Chapter 265) but should be used with caution to avoid toxic doses of salicylate. The enkephalinase inhibitor racecadotril, which is available in Europe but not currently in North America, also reduces diarrheal volume in children with acute gastroenteritis and is as effective as loperamide in adults but less likely to cause constipation.

Probiotics and Colostrum

Some probiotic preparations have been shown in small studies to improve symptoms when they are added to oral rehydration solution in children with infectious diarrhea but are not yet universally recommended. Powdered bovine colostrum, available as a nutritional supplement, can improve 48-hour outcomes in children under 2 with diarrhea, including rotavirus and enteric *E. coli*.[A1]

Antibiotics

Because most *E. coli* diarrhea is self-limited, the role of antimicrobial agents remains of secondary importance to rehydration except for patients with traveler's diarrhea (Chapter 265), in whom antibiotics clearly reduce the duration of symptoms.[A2] Since stool testing rarely is available in this setting, empirical options such as azithromycin (a single 1000-mg dose or 500-mg dose daily for 3 days), a fluoroquinolone (e.g., levofloxacin 500 mg single dose or daily for 3 days) or rifaximin (200 mg three times daily for 3 days) are recommended, with trimethoprim-sulfamethoxazole (1 double-strength tablet twice daily for 5 days) a somewhat less reliable alternative. Combining a single dose of fluoroquinolone (e.g., levofloxacin 500 mg) or rifaximin treatment with loperamide are very effective acute options but also are associated with acquisition of extended-spectrum β-lactamase *E. coli* at day 21, so the potential benefit of antibiotic treatment to reduce the duration of symptoms should be balanced against concerns for acquisition of drug-resistant bacteria.

Antimicrobials should not be used in enterohemorrhagic *E. coli* infection because of the possibility of increasing the production of Shiga-like toxin from bacteriophage carried within the organism, and thereby increasing the risk and severity of hemolytic-uremic syndrome (Chapter 158).[15] For persistent diarrhea due to enteroaggregative *E. coli*, ciprofloxacin (500 mg twice daily for 7 days) may be beneficial in patients with HIV/AIDS, but antibiotic treatment does not appear to be of benefit in otherwise healthy adults.

PREVENTION

Prevention of most *E. coli* enteric infections is ultimately related to basic economic development, adequate sanitary facilities, and sufficient availability of safe water. In areas where adequate water supplies and sanitary facilities are not available, exclusive breast-feeding for at least 6 to 12 months and hand hygiene reduce the likelihood of acquiring *E. coli* enteric infections. Consistent use of an alcohol-based hand sanitizer can reduce the incidence of traveler's diarrhea, although not acquisition of extended-spectrum β-lactamase–expressing organisms.[A3] Inexpensive, portable water filters can effectively reduce bacterial contamination and may reduce clinically significant diarrheal episodes in infants.[A4] Trials of hyperimmune bovine colostrum (following immunization of cows) have shown promising results in adult challenge models but are not yet clinically proven in a real-world setting.

Travelers to developing or tropical areas should avoid drinking untreated or unboiled water or ice and eating uncooked fruits or vegetables that may have been washed with highly contaminated water. Although a number of antimicrobial agents are effective during short periods when taken prophylactically, their effectiveness is ultimately limited by rapidly emerging resistance to antimicrobial drugs as well as by the potential side effects of their indiscriminate, widespread use (Chapter 265). Prophylactic probiotics may be of limited benefit for reducing the risk of traveler's diarrhea.[A5]

Sporadic enterohemorrhagic *E. coli* infections may be reduced by adequately cooking ground beef products to an internal temperature of at least 160° F (71° C) and by careful handwashing and other hygienic measures in daycare centers and nursing homes. Unfortunately, large outbreaks due to contaminated produce continue to occur and are frequently associated with items meant to be eaten raw (such as sprouts and vegetables). Irradiation of meats and some produce to reduce viable bacterial contamination is approved in the United States and Canada, but these foods are not widely sold at the present time.

Vaccine development appears to be the most promising strategy,[16] but no effective vaccine is licensed in the United States against intestinal pathogenic *E. coli*.

PROGNOSIS

Healthy adults and even adults with underlying comorbid conditions eventually always recover completely from most strains of enteric *E. coli*. Lethal infections with typical enteropathogenic *E. coli* may be associated with certain gene clusters, although it is too early to use such information for prognostic purposes. The greatest concern with enteric *E. coli* infections in developed areas is enterohemorrhagic *E. coli*/shigatoxigenic *E. coli*–associated hemolytic-uremic syndrome (Chapter 158), which develops in 3 to 7% of sporadic cases and as high as 20% of cases during outbreaks. Whereas most patients with hemolytic-uremic syndrome recover, they frequently require intensive medical care (including temporary hemodialysis), and as many as 30% of survivors have renal sequelae such as proteinuria, hypertension, reduced glomerular filtration rate, or, more rarely, dialysis dependence.[17]

On a global scale, the greatest impact of diarrheagenic *E. coli* is in children in low-income areas, where these otherwise self-limited infections can cause death from dehydration. Moreover, children who survive repeated episodes of infectious diarrhea (due to *E. coli* and other pathogens) may experience permanent deficits in growth and cognitive development, the full impact of which remains unknown.

281 ENTEROBACTERALES: NON-ENTERIC INFECTIONS AND MULTIDRUG RESISTANCE

AMY J. MATHERS

DEFINITION

The Enterobacterales are an order of gram-negative bacilli that are responsible for a broad range of infections in humans and in animals. They may be motile or nonmotile, depending on the species. They are aerobic or facultatively anaerobic in growth and have a predilection for inhabiting the gastrointestinal tract. Only extragastrointestinal manifestations of disease are discussed in this chapter. Enteric infections caused by *Escherichia coli* are discussed in Chapter 280.

The Pathogen

These organisms are now split into seven families all under the order Enterobacterales. Members of the Enterobacterales grow on a variety of solid media and are usually readily identified by clinical microbiology laboratories. Accurate speciation remains important in a clinical setting because of inherent differences in antibiotic susceptibility among species. Medically important members of the Enterobacterales (Table 281-1) include *Salmonella* (Chapter 284), *Shigella* (Chapter 285), and *Yersinia* (Chapter 288).

EPIDEMIOLOGY

The Enterobacterales, which are among the most common pathogens to infect humans worldwide, are responsible for community-acquired, hospital-acquired,

EPIDEMIOLOGY

The Enterobacterales, which are among the most common pathogens to infect humans worldwide, are responsible for community-acquired, hospital-acquired,

ABSTRACT

The Enterobacterales are an order of gram-negative bacteria that includes the genera *Enterobacter, Escherichia, Klebsiella, Salmonella, Shigella, Yersinia, Serratia,* and others. Having a predilection for inhabiting the gastrointestinal tract, the Enterobacterales are among the most common pathogens worldwide. They have in common the propensity for readily developing multidrug resistance at a rate that currently outstrips the rate of development of new antibiotics to combat them. Not only are multidrug-resistant strains of Enterobacterales becoming essentially endemic in some communities around the world, they have also permeated hospitals and other health care facilities. Antimicrobial multidrug resistance can be due to (1) the inherent properties of the pathogen (e.g., all *Enterobacter cloacae* are resistant to ampicillin because they carry β-lactamase in their chromosome) or (2) the pathogen's acquired antimicrobial resistance (e.g., by mutation or acquisition of genes for antimicrobial resistance through horizontal gene transfer). The properties of the pathogen and their resistance profiles have driven the spread of multidrug-resistant bacteria that challenge the control and management of patients with these infections.

and health care–associated infections. Examples of the last category include infections acquired in nursing homes and those associated with outpatient management of cancers or hematologic malignant disease. As several species are resident components of the flora of the gastrointestinal tract, isolates of Enterobacterales may represent examples of colonization rather than true infection when found in rectal swabs, urine, wounds, or respiratory secretions. In some regions, multidrug-resistant Enterobacterales have become endemic, thereby leading to substantial problems in the management of serious infections.[1] Although multidrug resistance in the United States is still largely health care–associated, resistant community-associated infections are continuing to emerge.[2]

E. coli is the most common cause of urinary tract infections, accounting for more than 80% of isolates from urine in most clinical situations (Chapter 263). *Klebsiella* spp and *Proteus mirabilis* are among other common causes of urinary tract infections. Enterobacterales infections in the urinary tract can range from uncomplicated cystitis to life-threatening acute pyelonephritis and sepsis. Complicated and recurrent urinary tract infections frequently occur in patients with urinary retention, anatomic abnormalities, or a need for frequent or chronic urinary catheterization. In some patients with complicated or recurrent urinary tract infections, multidrug-resistant Enterobacterales are seen.[3]

The spread of some strains of uropathogenic *E. coli* account for a disproportionate percentage of disease. For example, trimethoprim-sulfamethoxazole–resistant *E. coli* spread in a clonal fashion in the United States (e.g., "clonal group A" and *E. coli* O15:K52:H1). A widely spread *E. coli* clone, defined by multilocus sequence typing as sequence type 131 (ST131), is associated with resistance to ciprofloxacin and production of extended-spectrum β-lactamases.[4] This clone, which is typically associated with community-acquired urinary tract infections, has been detected in every inhabited continent.

Given that the niche of the most common Enterobacterales is in the gastrointestinal tract, it is not surprising that these bacteria are prominent as causes of abdominal infections. *E. coli* is the most common cause of both spontaneous bacterial peritonitis (occurring in cirrhotic patients [Chapter 139]) and bacterial peritonitis arising after visceral perforation (Chapter 128). Pyogenic liver abscesses (Chapter 137) and intra-abdominal abscesses may also be due to *E. coli*. *Klebsiella pneumoniae* is a leading cause of pyogenic liver abscesses (Chapter 137) and may also cause intra-abdominal infections, especially in patients who develop peritonitis after surgery for intra-abdominal disease.

The Enterobacterales may also cause pneumonia, although less commonly than urinary or abdominal infections. Enterobacterales respiratory tract infections are frequently hospital- and health care–associated pneumonias (Chapters 85 and 261) rather than community-acquired pneumonia. *K. pneumoniae*, which was prominently associated with community-acquired pneumonia (Chapter 85) in people with alcohol use disorder (Chapter 364), has declined in significance during the past few decades. Since the 1980s, a hypervirulent *K. pneumoniae* has emerged to cause serious disseminated infections, typically pyogenic liver abscess (Chapter 137), osteomyelitis (Chapter 251), and/or endophthalmitis (Chapter 391) in immunocompetent and otherwise healthy people. Although mostly antibiotic-sensitive at this time, some cases of multidrug-resistant *Klebsiella* have been identified.

Hospital-acquired pneumonia due to the Enterobacterales may be ventilator-associated (Chapters 85 and 261), and Enterobacterales rank as the third most common causes of ventilator-associated pneumonia after *Staphylococcus aureus* (Chapter 267) and *Pseudomonas aeruginosa* (Chapter 282). The Enterobacterales are not natural flora of the upper airway, but mucosal injury from ventilation and any prior infection, as well as exposure to antimicrobial agents, alters the airway microbiome to predispose patients to Enterobacterales pneumonia, including pneumonia from multidrug-resistant organisms such as *Enterobacter* sp. and *Serratia marcescens*.

Outbreaks of antibiotic-resistant *K. pneumoniae* infection in hospitals have been prominent for more than three decades. In the hospital setting, *K. pneumoniae* is usually the cause of peritonitis, pneumonia, or complicated urinary tract infection. Blood stream infection arising from another site of infection, from vascular catheters, or in association with neutropenia may also occur, but patient-to-patient transmission is otherwise rare.[5] In the past decade or so, with carbapenems considered the last line of reliable therapy for invasive infections, *K. pneumoniae* carbapenemase has become a substantial clinical and infection control issue in hospitals (Chapter 261).

PATHOBIOLOGY

Generally, Enterobacterales colonize the gastrointestinal lumen and exist in the environment, from where they are introduced into the genitourinary tract or other site to cause infection. At least 40 different virulence genes in *E. coli* can lead to extraintestinal infections. Among the virulence properties of these strains is the renowned ability of *E. coli* to adhere to uroepithelial cells. The ST131 *E. coli* clone is typically highly successful at causing extraintestinal infections. It belongs to "phylogenetic group" B2, which is known for extraintestinal pathogenic infections. In an evaluation of the ST131 clone, numerous extraintestinal virulence genes were found.

Mechanisms of Multidrug Resistance

Hard-to-treat and even untreatable infections with extended-spectrum β-lactamase and carbapenem-resistant Enterobacterales have emerged worldwide and have become a serious threat to global public health.[6] As with many infectious diseases, the emergence of highly resistant Enterobacterales is not evenly distributed, and several low- and middle-income countries have disproportionately high rates of resistance. The global spread of drug resistance is further facilitated by migration of refugees and pilgrimages.[7] In acute care hospitals in the United States, β-lactamase–resistant Enterobacterales comprise about 20% of all *Klebsiella* spp and *E. coli* isolates, and about 7% of *K. pneumoniae* isolates are carbapenem-resistant.[8] The stabilization and even decrease in infections with carbapenem-resistant Enterobacterales in acute care facilities in the United States has been attributed in part to initiatives designed to limit the use of broad-spectrum antibiotics and to prevent nosocomial transmission using detection and isolation strategies.

The molecular mechanisms of antibiotic resistance in the Enterobacterales can be either intrinsic or acquired (Table 281-2) (also see Chapter 266). Intrinsic resistance occurs when bacteria possess properties that naturally resist the action of an antimicrobial, often because of genes encoded in the chromosome of the wild-type bacterial species (e.g., all *Klebsiella* spp produce a β-lactamase that hydrolyzes ampicillin). Acquired resistance occurs by mutations in the chromosome, changes in gene expression, or acquisition of genes that confer resistance after horizontal gene transfer from other bacteria. From a molecular mechanism standpoint, bacteria resist antimicrobial agents in one of four ways: (1) alteration of antimicrobial uptake to the site of action (e.g., downregulating its expression of porins, which are nonspecific membrane channels, and thereby reducing its permeability to the antibiotic); (2) upregulating specific or multidrug-resistance pumps to increase the efflux to expel the antibiotic; (3) altering the target site so that the antimicrobial agent cannot efficiently bind (e.g., by target site mutation, acetylation, phosphorylation); or (4) destruction of the antibiotic by enzymatic activity (e.g., β-lactamases). Acquired resistance can then proliferate through (1) expansion of clonal lineages with antibiotic resistance gene mutations, including acquired β-lactamases and carbapenemases (i.e., clonal expansion) and/or (2) horizontal transfer of antibiotic-resistance genes through mobile genetic elements, such as plasmids or transposons, which can spread across strains and species.

TABLE 281-2 MECHANISMS OF ANTIBIOTIC RESISTANCE AND DRIVERS OF SPREAD OF MULTIDRUG-RESISTANT ENTEROBACTERALES

1. MECHANISMS OF ANTIBIOTIC RESISTANCE
Intrinsic Resistance
Bacterial species with inherent properties that naturally resist the action of an antibiotic often encoded in the chromosome of the wild-type population of a bacterial species (e.g., all *Klebsiella* spp produce a β-lactamase that hydrolyzes ampicillin)
Acquired Resistance
Development of resistance to an antimicrobial through mutation, altered regulation, or acquisition of genes of antimicrobial resistance through horizontal gene transfer
2. MECHANISMS OF ANTIMICROBIAL RESISTANCE
Prevent Access to the Antibiotic Target
Reduce influx of the antibiotic (e.g., downregulate porins) Increase efflux (e.g., overexpress specific or multidrug-resistance pumps)
Alter the Antibiotic Target
Change target structure through mutations to disable antibiotic binding Modify and protect the target by mutation or post-translational modification
Inactivate the Antibiotic
Enzymatically hydrolyze the antibiotic (e.g., β-lactamases, carbapenemases) Chemically alter the antibiotic to prevent antibiotic binding
3. DRIVERS OF SPREAD OF MULTIDRUG-RESISTANT BACTERIA
Clonal Expansion
Proliferation of clonal lineages with genes or mutations that can stably maintain antimicrobial resistance mechanisms
Horizontal Gene Transfer
Exchange of antimicrobial resistance genes between bacteria through mobile genetic elements, such as plasmids and transposons

Narrow-Spectrum β-Lactamases

Plasmids encoding resistance to ampicillin are widespread, and at least 40% of *E. coli* in most parts of the world now express a plasmid-mediated β-lactamase. Enterobacterales such as *Klebsiella* and *Enterobacter* spp have genes encoding β-lactamases inherent to their genome and are intrinsically resistant to ampicillin.

Extended-Spectrum β-Lactamases

Third-generation cephalosporins (such as ceftriaxone) are intrinsically active against all Enterobacterales. However, mutant genes encoding β-lactamases capable of inactivating third-generation cephalosporins have become widespread, initially because of point mutations in the plasmid-mediating β-lactamase that led to an altered amino acid sequence. In addition, many new types of extended-spectrum β-lactamase resistance have been acquired, including the cefotaximase-M type (CTX-M), which is now the most dominant extended-spectrum β-lactamase gene in *E. coli* in most regions of the globe.

Frequently, the ST131 *E. coli* clone produces a cefotaximase-M type of extended-spectrum β-lactamase (especially CTX-M-15). Although classic extended-spectrum β-lactamases are susceptible to β-lactamase inhibitors (e.g., clavulanic acid), many ST131 *E. coli* isolates produce an additional β-lactamase (OXA-1) that confers resistance to β-lactamase inhibitors. The antibiotic resistance phenotype of the ST131-positive *E. coli* is that the organisms are typically resistant to ceftriaxone, cefotaxime, fluoroquinolones, trimethoprim, trimethoprim-sulfamethoxazole, tetracyclines, and often penicillin-β-lactamase inhibitor combinations. Resistance to aminoglycosides is variable. The clone confers multidrug resistance by the presence of multiple antibiotic resistance genes, which are usually encoded on plasmids.

AmpC β-Lactamases

A number of genera within the Enterobacterales have a chromosomally encoded β-lactamase capable of producing resistance to all penicillins and all cephalosporins except for cefepime. In addition, these β-lactamases are not inhibited by β-lactamase inhibitors, such as clavulanic acid or tazobactam. These β-lactamases, which are known as AmpC β-lactamases or cephalosporinases, are not derived from narrower-spectrum parent β-lactamases. AmpC β-lactamases may be overproduced in the presence of certain antibiotics (i.e., the genes encoding the AmpC β-lactamases are "inducible"). *Enterobacter cloacae*, *Klebsiella aerogenes*, and *Citrobacter freundii* have inducible, chromosomally encoded AmpC β-lactamases. The challenge with these organisms is that they may initially test as susceptible to ceftriaxone but then begin making more AmpC and develop resistance while the patient is being treated, thereby resulting in therapeutic failure. AmpC β-lactamase genes, which have now been found on plasmids in *E. coli*, *Salmonella*, and other gram-negative bacteria, often lack regulation, thereby resulting in high-level continuous expression.

KPC, NDM, and Other Carbapenemases

With the emergence of extended-spectrum β-lactamase–producing Enterobacterales, carbapenems became widely used for the treatment of these organisms. However, a carbapenem-hydrolyzing β-lactamase capable of hydrolyzing penicillins, cephalosporins, aztreonam, and carbapenems has since been described globally in many genera of the Enterobacterales, such as *E. coli*, *K. pneumoniae*, *Enterobacter*, *Citrobacter*, and *Proteus* species. *K. pneumoniae* carbapenemase is the most frequently encountered in the United States and, despite its name, has been identified across many genera of Enterobacterales.

Another common carbapenem-hydrolyzing β-lactamase in Enterobacterales is the New Delhi metallo-β-lactamase, which is also a major cause of carbapenem resistance. The responsible enzyme is a typical metallo-β-lactamase that is not inhibited by β-lactamase inhibitors and cannot hydrolyze aztreonam. Many outbreaks of New Delhi metallo-β-lactamase–producing organisms have arisen in Southeast Asia and are often the cause of hospital outbreaks. These New Delhi metallo-β-lactamase-producing organisms also have been found in drinking water in India and in food-producing animals in China. Other carbapenem-hydrolyzing β-lactamases seen in Enterobacterales include the OXA-48-like types, which were originally found in Europe and the Middle East but have continued to spread to other parts of the world, as well as a variety of other metallo-β-lactamases. These enzymes all share the ability to render Enterobacterales resistant to carbapenems and many other β-lactam antibiotics, thereby making therapeutic decisions very challenging.

CLINICAL MANIFESTATIONS

The clinical manifestations of urinary tract infections (Chapter 263), pneumonia (Chapter 85), intra-abdominal infections (Chapter 128), and blood stream infections (Chapter 94) due to the Enterobacterales are described in other chapters.

DIAGNOSIS

Enterobacterales are readily grown in clinical microbiology laboratories after collection of appropriate specimens. Examination of the Gram stain enables a rapid identification of gram-negative bacilli from gram-positive pathogens. Molecular methods can rapidly detect many specific Enterobacterales and can also identify several of the β-lactamase genes from a positive blood culture soon after the completion of the Gram stain.[9] These results can guide empiric therapy with a carbapenem or a novel antimicrobial agent while awaiting final speciation results from culture as well as detailed susceptibility testing.

TREATMENT

Urinary Tract Infections

Treatment depends on the site of infection and the extent of antibiotic resistance. Uncomplicated cystitis due to *E. coli* and the other Enterobacterales (Chapter 263) may be treated with empiric orally administered fosfomycin, nitrofurantoin, quinolones, or trimethoprim-sulfamethoxazole if susceptible. Fosfomycin is indicated only in the setting of uncomplicated cystitis caused by *E. coli*. Empirical parenteral choices for more severe infections may include third-generation cephalosporins, fluoroquinolones, aminoglycosides, and carbapenems and should be based on local rates of resistance of the most commonly treated organisms.

Extended-Spectrum β-Lactamase–Producing Organisms

In vitro, the carbapenems (including imipenem, meropenem, doripenem, and ertapenem) have the most potent activity against extended-spectrum β-lactamase–producing organisms. To avoid overuse, carbapenem-sparing strategies should be used when feasible, even for extended-spectrum lactamase infections. Observational data suggest that quinolones or, in some instances, cefepime may be reasonable alternatives, depending on the degree and type of resistance. However, carbapenems should be regarded as the drugs of choice for serious infections with extended-spectrum β-lactamase–producing organisms.[10] For example, meropenem is generally the treatment of choice for serious infections due to extended-spectrum β-lactamase producers.[A1] The ability to

TABLE 281-3 NOVEL β-LACTAM OR β-LACTAMASE INHIBITORS APPROVED TO COMBAT MULTIDRUG-RESISTANT ENTEROBACTERALES*

MEDICATION	ACTIVITY BY ENZYME TYPE				
	Class A extended-spectrum β-lactamases	*Klebsiella pneumoniae* carbapenemases	AmpC cephalosporinases	Metallo-β-lactamases	Oxacillinases
Ceftazidime-avibactam	+	+	+	-	+/-
Imipenem-relebactam	imipenem alone is active, so relebactam is not needed	+	+	-	+/-
Cefiderocol	+	+	+	+	+
Meropenem-vaborbactam	meropenem alone is active, so vaborbactam is not needed	+	-	+/-	-
Ceftolozane-tazobactam	+	-	-	-	-

*Dosing should be supervised by experts for specific clinical scenarios.

use ertapenem once daily makes it potentially useful in serious infections with extended-spectrum β-lactamase producers in nursing home residents or patients who can continue parenteral therapy out of the hospital. There is no evidence that combination therapy involving a carbapenem is superior to use of a carbapenem alone for extended-spectrum β-lactamase producers.

Carbapenem-Resistant Organisms

Treatment of carbapenem-resistant organisms is challenging because they may lack susceptibility to all traditional β-lactam antibiotics (including penicillins, cephalosporins, aztreonam, and carbapenems), fluoroquinolones, and aminoglycosides.[11] Carbapenemase-producing organisms may sometimes appear susceptible to carbapenems such as meropenem and imipenem (although they are almost always recognized as resistant to ertapenem), but these antibiotics should not be relied upon when a carbapenemase is present. Colistin monotherapy (5 mg/kg once followed by 1.67 mg/kg every 8 hours) is a potential option.

Newer agents for multidrug-resistant Enterobacterales are designed to address the worldwide challenge. The majority of those new drugs pair unique β-lactamase inhibitors, which target the enzymes driving resistance, with an already approved broad-spectrum β-lactam antimicrobial. These agents have generally undergone an expedited approval process, so clinical trial data are not as robust as for prior antimicrobial agents. Ceftazidime/avibactam is active against *K. pneumoniae* carbapenemase, AmpC, and OXA-48–producing bacteria, although the development of resistance may be a concern in patients who have infections with a high bacterial burden[A3] (see Table 281-3). Meropenem/vaborbactam is active against *K. pneumoniae* carbapenemase-producing bacteria.[A4] Imipenem-cilastatin-relebactam also has activity against *K. pneumoniae* carbapenemase-producing Enterobacterales.[A5] None of these new agents has activity against metallo-β-carbapenemases (e.g., Verona integron-encoded metallo-β-lactamase and New Delhi metallo-β-lactamase), but cefiderocol,[12] which is a novel siderophore, should be able to avoid hydrolysis across all types of the carbapenemases, including metallo-β-lactamases.[A6]

Non-β-lactam antibiotics include eravacycline, omadacycline, plazomicin, and delafloxacin, all of which have activity against gram-negative bacteria that produce extended-spectrum β-lactamases; however, each agent should be used with caution under the oversight of an infectious disease specialist. Several additional agents are in the late stages of development.

PREVENTION

Prevention of hospital-acquired outbreaks of multidrug-resistant Enterobacterales depends on basic infection control principles (Chapter 261). First, if a focus of infection (e.g., an infected bronchoscope) exists in the hospital environment, it should be removed, and all medical devices and equipment must be appropriately sterilized. Persistent reservoirs in the hospital environment, such as wastewater plumbing systems, must be identified and mitigated.

However, transient carriage from an infected or asymptomatically colonized patient to another on the hands of health care workers appears to be the most important means of transfer of multidrug-resistant Enterobacterales. The hands of health care workers are presumably colonized by contact with the skin, stool, or bodily fluids of the infected patient or by contact with a contaminated environment around the patient. Hand carriage by health care workers is usually eliminated by good hand hygiene and use of alcohol-based agents.

In some hospital sites with ongoing issues with extended-spectrum β-lactamase, *K. pneumoniae* carbapenemase, or New Delhi metallo-β-lactamase–producing organisms, more than 30% of patients have gastrointestinal tract colonization with these organisms at any one time. These colonized patients should be placed in contact precautions. An isolation strategy of careful contact precautions in a multibed room can be as effective as contact precautions in a single-bed room.[A7] Adherence with contact isolation precautions and hand hygiene must be high to maximize the effectiveness of these interventions.

Antimicrobial exposure is known to be a risk factor for multidrug-resistant organisms because it eliminates susceptible flora, thereby selecting for resistant bacteria. A variety of interventions have tried to reduce the use of specific broad-spectrum antibiotics with variable success. Prudent use of all antibiotic classes with an emphasis on reducing duration of antibiotic use may be more useful than restrictions on individual classes of antibiotics.

PROGNOSIS

Many Enterobacterales tend to infect patients who have other comorbid conditions or who are immunosuppressed, so infected patients often have an inherently poor prognosis, which makes treatment of any infection more challenging. The prognosis of infection with the Enterobacterales depends on multiple factors, such as site of infection, presence of underlying diseases, control of the infection source, and access to needed newer antimicrobial agents. At one extreme, inadequate orally administered antibiotic therapy for uncomplicated urinary tract infections due to an extended-spectrum β-lactamase producer may have no impact on mortality, although it may have an impact on duration of symptoms and need for parenteral therapy for treatment failure. Mortality can be as high as 50% among hospitalized patients who develop blood stream infections with carbapenem-resistant Enterobacterales. At the other extreme, patients in an intensive care unit with serious infections due to KPC or NDM producers may have an in-hospital mortality rate exceeding 70%. By comparison, in-hospital mortality rates are 20 to 30% in similar patients who are not infected with *K. pneumoniae* carbapenemase or New Delhi metallo-β-lactamase producing bacteria.

282 *PSEUDOMONAS* AND *BURKHOLDERIA* INFECTIONS

MATTHEW E. FALAGAS AND PETROS I. RAFAILIDIS

PSEUDOMONAS INFECTION

DEFINITION

Infections due to *Pseudomonas* spp are caused by members of the family Pseudomonadaceae. The Pseudomonadaceae is a group of gram-negative rods, including *P. aeruginosa*, the most frequently recovered human pathogen in the family. Other *Pseudomonas* spp include *P. putida, P. alcaligenes, P. fluorescens, P. luteola, P. mendocina, P. oryzihabitans, P. pseudoalcaligenes, P. stutzeri, P. chlororaphis, P. delafieldii, P. kingii, P. pertucinogena*, and *Pseudomonas* CDC group 1.

The Pathogens

P. aeruginosa is a gram-negative, lactose nonfermenting, straight or slightly curved rod with a length ranging from 1.5 to 7 μm and a width of 0.5 to 1.0 μm. It is catalase positive, oxidase positive, and motile with one or more polar flagella. Most species oxidize glucose and reduce nitrate to nitrite or nitrogen gas. It has the ability to grow at 42° C. This pathogen contains a polysaccharide capsule along with lipopolysaccharides, pili, and flagella. The organism includes toxins such as exotoxin A, pyocyanin (blue or blue-green pigment), pyorubin (red or red-brown pigment), pyomelanin (black pigment), and pyoverdin (yellow-green pigment). *P. aeruginosa* is notorious for its ability to acquire resistance genes and to spread by horizontal transfer. The microorganism possesses a diversity of mechanisms that promote its survival, adaptation, and resistance to multiple classes of antibiotics that make it an emerging worldwide public health threat.

EPIDEMIOLOGY

P. aeruginosa is one of the most common pathogens in health care–associated infections.[1] The main types of infections associated with *P. aeruginosa* in hospital settings are ventilator-associated pneumonia, primary bacteremia associated with central venous catheters, and secondary bacteremias due to infections elsewhere in the body, urinary tract infections, and surgical site infections. Data from the National Healthcare Safety Network at the Centers for Disease Control and Prevention indicate that *P. aeruginosa* is responsible for about 8% of all health care–associated infections in the United States and is the fourth most frequent infectious agent. *P. aeruginosa* can survive in environments that have only minimal nutritional components, and it can colonize moist surfaces of the axilla, ear, and perineum. It is also isolated from other moist, inanimate environments in hospitals, including water in sinks and drains, mechanical ventilation equipment, dialysis equipment, toilets, showers, hydrotherapy pools, mops, water for flowers, and sometimes cleaning solutions.

Strains of *P. aeruginosa* resistant to multiple classes of antibiotics, including quinolones and β-lactams, are a major cause of morbidity and mortality worldwide. During a relatively short time, a multidrug-resistant *P. aeruginosa* strain can spread through neighboring countries. The use of broad-spectrum antibiotics is certainly a risk factor for the development of multidrug-resistant *P. aeruginosa*, as are deficiencies in infection control practices.

A range of hosts are particularly prone to infections by this pathogen: patients with neutropenia (Chapter 153), burns (Chapter 97), cystic fibrosis (Chapter 77), chronic obstructive pulmonary disease (COPD; Chapter 76), cancer, transplant recipients, diabetes (Chapter 210), and AIDS (Chapter 358). Patients with compromised humoral (hypogammaglobulinemia) or cellular (steroid treatment) immunity, due to a disease or its treatment, as well as patients with foreign bodies (e.g., vascular grafts, orthopedic implants) are also more vulnerable to *P. aeruginosa* infections.

Community-acquired *P. aeruginosa* infection is related to exposure to water by the use of hot tubs, whirlpools, swimming pools, spas, and other types of baths, as well as to the use of contact lenses, particularly the extended-wear variety. Puncture wounds, including through tennis shoes, can give rise to *P. aeruginosa* infection. *P. aeruginosa* endophthalmitis (Chapter 391) after eye trauma can result in visual compromise, and *P. aeruginosa* endocarditis (Chapter 61) is frequently found in intravenous injection drug users.

PATHOBIOLOGY

Pathogenesis and Pathophysiology

Innate immunity, primarily through inflammatory cytokine production and phagocytic clearance by neutrophils and macrophages, is the key to endogenous control of *P. aeruginosa* infection.[2] *P. aeruginosa* binds to the cystic fibrosis transmembrane conductance regulator (CFTR), which is a channel involved in chloride movement across the cell. Release of interleukin-1 and signaling through the interleukin-1 receptor and adaptor molecule MyD88 occur. NF-κB is translocated, followed by transcription of NF-κB–dependent genes and the production of interleukin-6, interleukin-8, and intercellular adhesion molecule 1. Polymorphonuclear neutrophils are recruited to infected tissue to resolve the infection. Patients with cystic fibrosis have a defective CFTR and thus cannot mount a normal defensive response to *P. aeruginosa*.

Bacterial Factors

P. aeruginosa survives in aquatic as well as in soil environments. Several factors, including flagella, pili, exopolysaccharides, phospholipases, proteases, endotoxins, secreted toxins (types I, II, II, IV, and VI), exotoxins, and iron-binding proteins, are involved in pathogenesis (E-Table 282-1). *Pseudomonas* produces high levels of an extracellular mucoid polysaccharide called alginate, which is the main constituent of the glycocalyx allowing growth in a biofilm. Furthermore, the expression of O side chains on the bacterium's lipopolysaccharide prevents lysis by complement. Bacterial toxins and enzymes kill immune cells and invade and degrade tissues . Exotoxin A, an adenosine diphosphate–ribosylating toxin, has activity similar to that of diphtheria. The production of this cellular toxin is affected by iron levels. *P. aeruginosa* uses pyoverdin and pyochelin, typical siderophore systems, to acquire iron.

P. aeruginosa can induce hemolysis by PlcHR, a hemolytic phospholipase C. A nonhemolytic phospholipase C, PlcN, is also made by *P. aeruginosa* strains. *P. aeruginosa* type III secretion systems allow direct injection of bacterial toxins into eukaryotic cells and disrupt cellular trafficking by inhibiting the actin cytoskeleton and by affecting protein synthesis. *Pseudomonas* communicates with other members of its microbial community through quorum sensing, thereby leading to the formation of biofilms, which limit penetration of antibiotics and make it difficult to eradicate the organism. Pili and flagella, though not considered classical components of the biofilm, are important for its maturation. Furthermore, *P. aeruginosa* and *S. aureus* coinfect the lung and chronic wounds, where they form multispecies biofilms, in which *P. aeruginosa* can outcompete *S. aureus*.[3]

Both transferable (such as β-lactamase production) and intrinsic (mutation-driven) mechanisms confer *Pseudomonas* resistance to antibiotics, including carbapenems. Transferable resistance to aminoglycosides entails modification of aminoglycosides through phosphoryltransferases, acetyltransferases, nucleotidyltransferases, or ribosomal methyltransferases (RmtA, RmtB, RmtC, RmtD, and ArmA). Chromosomally mediated resistance is related to mutations in the quinolone resistance-determining region of gyrase A and the topoisomerase IV gene *parC*, which hamper the attack of fluoroquinolones on the bacterium. Aminoglycoside-inactivating enzymes are related to the *P. aeruginosa* chromosome and involve 3-*N*-aminoglycoside acetyltransferases or nucleotidyltransferases. Impermeability resistance to aminoglycosides is also chromosomally mediated.

Pathology

The pathologic spectrum of *P. aeruginosa* infections depends on the site afflicted. Hemorrhage and necrosis may be present in severe *Pseudomonas* infections, such as in pneumonia and endocarditis. In ecthyma gangrenosum, bacteria invade the arteries and veins of the skin, with little accompanying inflammation because of the paucity of pus in these skin lesions.

CLINICAL MANIFESTATIONS

Among the constellation of manifestations in the clinical spectrum of *P. aeruginosa* infections, no symptoms or signs effectively discriminate *P. aeruginosa* infection from infections by other pathogens. Even ecthyma gangrenosum can be caused by other bacteria, such as *Staphyloccocus aureus* (Chapter 267) or *Citrobacter freundii* (Chapter 281).

Febrile Neutropenia

P. aeruginosa is a key infectious agent of concern in patients who have febrile neutropenia (Chapters 153 and 260).[4] It is the organism against which empirical coverage must always be included. The classic clinical syndromes in febrile

ABSTRACT

Pseudomonas aeruginosa is one of the most common pathogens among health care–associated infections. A wide spectrum of clinical manifestations ranges from eye, ear, urinary tract, and soft tissue infections to joint, bone, central nervous system, respiratory tract, endovascular, and intra-abdominal infections to a cause of febrile neutropenia and septic shock. Strains resistant to multiple classes of antibiotics, including quinolones and β-lactams, are a major cause of morbidity and mortality worldwide. Management of infections caused by organisms at one time classified as Pseudomonads, including melioidosis caused by what is now renamed *Stenotrophomonas maltophilia*, is also discussed in the text.

E-TABLE 282-1 VIRULENCE FACTORS FOR *PSEUDOMONAS AERUGINOSA*

LOCATION OR CLASS	EXAMPLES	ACTIVITY/EFFECTS ON HOST
Cell surface	Alginate	Antiphagocytic, resists opsonic killing
	Lipopolysaccharide	Endotoxic, antiphagocytic, avoids preformed antibody to previously encountered O antigens
	Pili (produced by type IV secretion)	Twitching motility, biofilm formation, adherence to host tissues
	Flagella	Motility, biofilm formation, adherence to host tissues and mucin components
	Injection of type III secretion factors	PcrG, PcrV, PcrH, PopB, and PopD proteins form injection bridge for type III effectors
Outer membrane	Siderophore receptors	Provides iron for microbial growth and survival
	Efflux pumps	Remove antibiotics
Secretion systems		
Type II	Elastase, lipase, phospholipases, chitin-binding protein, exotoxin A, and others	Variety of proteolytic, lipolytic, and toxic factors; degrade host immune effectors
Type III	ExoS, ExoT, ExoU, ExoY	Intoxicates cells (ExoS, ExoT); cytotoxic (ExoU); disrupts actin cytoskeleton
Type VI	Cytoplasmic and membrane-associated proteins, ATPases, lipoproteins, Hcp1 protein	Poorly characterized but found in animal studies to be needed for optimal virulence, particularly in chronic infection
Iron acquisition	Pyoverdin, pyochelin	Scavenge iron from the host for bacterial use
Secreted toxins	Hemolysins, rhamnolipid phospholipases	Kill leukocytes, hemolysis of red cells, degrade host cell surface glycolipids
Secreted oxidative factors	Pyocyanin, ferripyochelin	Produce reactive oxygen species: H_2O_2, O_2^- Inflammatory, disrupts epithelial cell function
Quorum sensing	LasR/LasI, RhlR/RhlI, PQS	Biofilm formation, regulation of virulence factor secretion

ATPases = adenosine triphosphatases; PQS = *Pseudomonas* quinolone signal.

neutropenic patients are bacteremia, pneumonia, and soft tissue infection, mainly manifested as ecthyma gangrenosum (Fig. 260-5).

Bacteremia

Bacteremia is usually caused by primary infection at a specific site, such as pneumonia, urinary tract infection, complicated intra-abdominal tract infection (peritonitis, abscess), or endocarditis. Manifestations can include those of sepsis and septic shock (i.e., fever, tachycardia, tachypnea, hypotension, and mental status changes ranging from confusion to coma; Chapter 94).[5] Multiorgan failure with adult respiratory distress syndrome (Chapter 90) and acute renal failure (Chapter 106) may occur and be accompanied by coagulation defects (e.g., disseminated intravascular coagulation; Chapter 161).

Eye Infections

Keratitis (Chapter 391) is associated with wearing contact lenses, especially extended-wear lenses, but any form of trauma, including surgery and burns, may predispose to keratitis by direct inoculation of *Pseudomonas*.[6] Pain and redness are cardinal manifestations, the entire cornea can be opacified, and perforation sometimes occurs. *P. aeruginosa* keratitis is a medical emergency because of the speed with which it can progress and lead to loss of vision.

Fulminant endophthalmitis (Chapter 391) may result from penetrating injuries, surgery, perforation of a corneal ulcer, or seeding from bacteremia. Manifestations include severe pain, chemosis, decreased visual acuity or even loss of vision, anterior uveitis, and vitreous involvement.

Other rarer eye infections include blepharoconjunctivitis, corneal ulcer, scleritis, and canaliculitis (both primary and plug-related). *P. aeruginosa* bacteremia also may lead to orbital cellulitis and gangrenous necrosis of the eyelids in neutropenic patients.

Ear Infections

Acute otitis externa (Chapter 394) with otalgia, which is commonly seen in children, results from infection of moist, macerated skin of the external ear canal. The source of the organism is likely to be hot tubs or swimming pools (swimmer's ear), particularly if they are not sufficiently chlorinated.

In patients who have diabetes or chronic HIV infection, so-called malignant otitis externa can present with fever, drainage, nerve palsies, hoarseness, dysphagia, pain on traction of the pinna, facial paralysis, and altered mental status owing to infection at the junction of bone and cartilage in the meatus.[7]

Acute Respiratory Tract Infections

P. aeruginosa is a frequent cause of ventilator-associated pneumonia and hospital-associated pneumonia (Chapters 85 and 261), accounting for about perhaps 20% of cases.[8] Clinical manifestations may include fever, productive cough, crackles, rhonchi, central cyanosis, tachypnea, use of accessory respiratory muscles, signs of septic shock, and multiorgan failure.

Community-acquired *P. aeruginosa* pneumonia also occurs, particularly in patients who have underlying structural lung disease such as COPD (Chapter 76) or bronchiectasis (Chapter 78), are immunocompromised,[9] or who have been previously treated with antibiotics.

Chronic Respiratory Tract Infections

P. aeruginosa is responsible for chronic airway infections, mainly with cystic fibrosis[10,11] and COPD. *P. aeruginosa* also can cause a diffuse panbronchiolitis, mainly in Asian populations, manifested by persistent cough and exertional dyspnea; at least 50 to 100 mL/day of sputum; chronic paranasal sinusitis; coarse crackles; bilateral, diffuse, small nodular shadows on a plain chest radiograph or centrilobular micronodules on chest computed tomography; evidence of airway obstruction, hypoxemia, and an elevated cold hemagglutinin titer.

Bone and Joint Infections

P. aeruginosa is among the main causative pathogens of bone infections (Chapter 251) in patients who have indwelling devices or prostheses[12] and in intravenous drug users (Chapter 365), in whom vertebral osteomyelitis, sacroiliac septic arthritis, and septic arthritis of the sternoclavicular joint are seen, sometimes, but not always, with pain and positive blood cultures. In vertebral *P. aeruginosa* osteomyelitis, clinical manifestations are more indolent than in staphylococcal osteomyelitis and often range from weeks to months. The affected region may be tender with a decreased range of motion. Low-grade fever is common.

Pseudomonas osteomyelitis (Chapter 251) of the foot most frequently follows puncture wounds through sneakers. The main manifestation is pain in the foot, sometimes with superficial cellulitis around the puncture wound and tenderness on deep palpation of the wound. Patients with Charcot arthropathy (neuropathic joint) and diabetes are especially at risk for *P. aeruginosa* bone infection.

Central Nervous System Infections

Involvement of the central nervous system is almost always secondary to a surgical procedure[13] or penetrating head trauma and is rare after bacteremia. The entities seen most often are postoperative or post-traumatic meningitis (Chapter 381), subdural empyema (Chapter 382), and epidural infections resulting from initial contamination of access areas. Brain abscess secondary to embolic disease from endocarditis may be seen. Extension of the infection in necrotizing malignant otitis to the brain heralds an ominous clinical course.

Urinary and Genital Tract Infections

P. aeruginosa urinary tract infections (cystitis, pyelonephritis, renal/perirenal abscess [Chapter 263]) usually occur as a complication of the presence of a foreign body, such as a catheter or stent in the urinary tract, an obstruction (mainly stone or malignant neoplasm) of the urinary system, or after instrumentation or surgery in the urinary tract. However, *P. aeruginosa* urinary tract infections can occur in any patient, often associated with bacteremia. Genital tract infections due to *P. aeruginosa* include epididymitis, orchitis, epididymo-orchitis (with or without abscess), and prostatitis (with or without abscess).

Skin and Soft Tissue Infections, Including Burns

P. aeruginosa causes a variety of skin manifestations, including ecthyma gangrenosum in neutropenic patients.[14] These small, round lesions can occur (see Fig. 260-5) either isolated or as aggregates, especially on the limbs and the perineum. The lesions evolve from vesicles to nodules that become hemorrhagic and necrotic, and eventually ulcerate. This evolution may lead to a spectacular increase in size from less than 1 to more than 10 cm in a period of less than 24 hours. However, ecthyma can also be caused by other gram-positive or gram-negative bacteria (*S. aureus, S. pyogenes, Aeromonas* spp, *Serratia* spp, *S. maltophilia*) or fungi (*Candida* spp, *Aspergillus* spp, *Mucor* spp, and *Fusarium* spp).

Maceration of normal skin, such as from soaking in a hot tub, can lead to superficial infection (Fig. 406-27) and then potentially to soft tissue infection and even hematogenous dissemination. Folliculitis and other papular or vesicular lesions have also been attributed to *P. aeruginosa*. Other types of skin and soft tissue involvement are cellulitis, abscesses, toe web infection (webspace intertrigo), paronychia usually in association with green nail syndrome, and myositis. Secondary infection of chronic skin ulcers can also occur.

Burn wound infections (Chapter 97) by *P. aeruginosa* constitute one of the most significant problems caused by this organism. A distinct clinical picture of sepsis, in which high colony counts of *P. aeruginosa* exceed 10^5 organisms per gram of tissue, is the defining feature. Patients generally exhibit the progressive formation of a black necrotic eschar, with or without bacteremia. Wound infection can also occur in pressure ulcers and at surgical sites.

Endovascular Infections

P. aeruginosa may cause endovascular infections, including infective endocarditis (Chapter 61) mainly of native valves but also of prosthetic ones. Mycotic aneurysms (Chapter 377) may occur in the setting of endocarditis. In intravenous drug users (Chapter 365), the source is generally contaminated material, needles, or other paraphernalia; in this population, *P. aeruginosa* may even lead to outbreaks of endocarditis. The manifestations of *P. aeruginosa* endocarditis resemble those of other forms of acute endocarditis, except that it appears to be more indolent than *S. aureus* endocarditis. *P. aeruginosa* may also lead to septic thrombophlebitis.

Intra-abdominal and Gastrointestinal Infections

P. aeruginosa can be involved in complicated intra-abdominal infections, usually as part of a polymicrobial infection. It is recovered in cases of secondary peritonitis, tertiary peritonitis, peritonitis associated with continuous ambulatory peritoneal dialysis (Chapter 117), spontaneous bacterial peritonitis (Chapter 139), and intra-abdominal abscesses. Gastrointestinal infections due to *P. aeruginosa* include necrotizing enterocolitis in children and typhlitis in neutropenic patients (neutropenic enterocolitis; Chapter 128).

Uncommon *P. aeruginosa* Infections

P. aeruginosa can cause toe web infections; paronychia, the "green nail syndrome" as a result of diffusion of pyocyanin into the nail bed; and *Pseudomonas* hot-foot syndrome, which is manifested with tender plantar nodules.

Infection Due to *Pseudomonas* spp Other than *P. aeruginosa*

P. fluorescens may lead to bacteremia associated with central venous catheters or transfusion-related bacteremia. Notably, a multistate outbreak occurred in the United States owing to contaminated heparinized saline flush. Reports of *P. stutzeri* infections include peritonitis, meningitis, endocarditis, pneumonia, bacteremia, and endophthalmitis. *P. putida* has been reported as a causative pathogen in bacteremia, pneumonia, cholecystitis, cholangitis, and skin and soft tissue infections.

DIAGNOSIS

Multiplex polymerase chain reaction (PCR) tests are especially valuable in intensive care unit settings, where rapid diagnosis is important.[15] PCR in this setting has a reported sensitivity of 96.5% and a specificity of 99.7%, and it can also provide information on antibiotic susceptibility.[16] However, the role of multiplex PCR is still evolving, so the definitive diagnosis of *P. aeruginosa* typically depends on the culture of the pathogen from various human biologic samples or fluids (blood, urine, sputum, bronchoalveolar lavage, pleural, cerebrospinal fluid, wound, burn, pus) pertinent to the clinical presentation. A Gram stain of the pertinent biologic sample can often provide interim clues while awaiting culture results. Computerized tomography of the brain, chest, abdomen, pelvis or magnetic resonance imaging of the brain, spine, or symptomatic bony area can document the presence of infection but cannot corroborate *P. aeruginosa* as the potential pathogen.

Three sets of blood cultures in the time span of 1 hour and expeditious use of echocardiography are recommended for the diagnosis of endocarditis. For ventilator-associated pneumonia, endotracheal aspiration with semi-quantitative cultures is preferred over invasive sampling (performing bronchoscopy for bronchoalveolar lavage or obtaining samples through a protected specimen brush or blind bronchial sampling).

In patients with *Pseudomonas* otitis, it is the only organism cultured in one third of patients but part of a polymicrobial infection in the others. In malignant otitis externa, culture specimens should be taken from the external auditory canal. Computed tomography or magnetic resonance imaging findings include temporomandibular joint destruction, infratemporal fossa or nasopharyngeal soft tissue involvement, and evidence of meningitis or empyema. In the setting of osteomyelitis, the acquisition of bone through fine-needle aspiration guided by CT or bone biopsy and culture through open biopsy may be necessary if blood cultures are sterile. The cerebrospinal fluid profile of *P. aeruginosa* meningitis is that of pyogenic meningitis. The differential diagnosis includes other bacterial and fungal pathogens that can lead to the same spectrum of diseases, especially in the hospital environment (Chapter 261). External otitis, infection after a nail injury, or infection after immersion in water can provide some important clues to suggest *P. aeruginosa*. Other clues can come from knowing that the patient has a high pretest probability of having a *P. aeruginosa* infection (e.g., neutropenic patients, patients with burns and wounds, cystic fibrosis patients, patients who have medically inserted equipment or foreign bodies).

At times, clinical acumen is needed to differentiate frank infection due to *P. aeruginosa* from colonization. Clues include local symptoms and signs (pain, erythema, necrosis, exudate, edema, loss of function, dysuria, productive cough) or systemic symptoms and signs (fever, hypotension, tachycardia, dyspnea, hypoxia, rash, organ failure, radiologic change of previous imaging) of infection.

TREATMENT

In neutropenic patients, the possibility of *P. aeruginosa* infection requires empirical therapy as would be used for *Pseudomonas* bacteremia. In other high probability settings (e.g., patients who have burns, cystic fibrosis, inserted foreign bodies, or classic eye, ear, or skin findings), antibiotic coverage for *Pseudomonas* is indicated until microbiologic data from either cultures or PCR tests exclude pseudomonas and establish an alternative cause. A de-escalation protocol can then be performed to narrow the antibiotic spectrum.

Treatment of *P. aeruginosa* Bacteremia

Antibiotic Options

For severe infections associated with respiratory failure (Chapter 90) and septic shock (Chapter 94), empiric combination therapy[17] for *P. aeruginosa* bacteremia should be started within 1 hour. Options include an antipseudomonal β-lactam plus either an aminoglycoside or a fluoroquinolone within 1 hour. Alternatives associated with less toxicity without compromising effectiveness are monotherapy with β-lactam/β-lactamase inhibitor (piperacillin-tazobactam) or an antipseudomonal carbapenem (meropenem or imipenem-cilastatin). However, combination therapy should not be routinely used for ongoing treatment of most other serious infections, including bacteremia and sepsis without shock or for neutropenic sepsis/bacteremia.[18]

Local in vitro antimicrobial susceptibility data regarding the level of resistance of local clinical isolates of *P. aeruginosa* to various antibiotics should guide the choice of this initial empiric therapy.[19] About 25% of *P. aeruginosa* strains causing bloodstream infections in hospitalized patients are resistant to fluoroquinolones, about 20% are resistant to carbapenems, and about 15% are resistant to piperacillin-tazobactam.[20] Depending on the antibiotic susceptibility of *P. aeruginosa* isolates routinely found in a specific setting, one of the following regimens would be appropriate for *P. aeruginosa* bacteremia, provided renal function as assessed by creatinine clearance is relatively normal (>50 to 60 mL/minute): intravenous (IV) piperacillin-tazobactam (3.375 to 4.5 g infused over 4 hours every 6 to 8 hours), ceftazidime (2 g every 8 hours), cefepime (2 g every 8 to 12 hours), meropenem (1 to 2 g infused over 3 hours every 8 hours), imipenem (0.5 to 1 g every 6 hours), doripenem (0.5 g [1-hour infusion] every 8 hours), or aztreonam (1.5 to 2 g every 6 to 8 hours, used mainly for patients with β-lactam allergy). The addition of an aminoglycoside to these regimens depends on the level of resistance to β-lactam antibiotics seen at any given institution. If administration of a second drug is indicated, amikacin (15 mg/kg every 24 hours) may be added to the β-lactam antibiotic therapy. Addition of ciprofloxacin (400 mg IV every 8 to 12 hours) instead of an aminoglycoside can also be considered. For bacteria that are resistant to all β-lactams (including carbapenems) and quinolones, either ceftazidime-avibactam (2.25 g every 8 hours administered over 3 hours) or imipenem-cilastatin-relebactam (1.25 g every 6 hours) is recommended.[21]

If the *Pseudomonas* is resistant to carbapenems, options include polymyxin B, fosfomycin, and several forms of colistin.[22] For polymyxin B, a loading dose of 20,000 to 25,000 IU/kg over 1 hour should be followed by 1.25 to 1.5 mg/kg (equivalent to 12,500 to 15,000 IU/kg) every 12 hours, infused over 1 hour. A parenteral formulation of fosfomycin sodium (8 g every 8 hours infused over 6 hours) also can be used, only in combination with other antibiotics with an antipseudomonal spectrum. The several forms of colistin require careful dosing under the guidance of an infectious diseases expert.

Current guidelines then advise de-escalation to the most appropriate single-agent therapy in response to the susceptibility profile or to clinical improvement or resolution of the infection after 3 to 5 days. The total duration of treatment of bacteremia is usually approximately 14 days in non-neutropenic patients. Eight to 10 days may be equally efficacious in uncomplicated bacteremia, but longer courses are appropriate for patients with undrainable foci of infection, endocarditis, osteomyelitis, abscesses of the brain or kidneys, immunologic deficiencies including neutropenia, or a slow clinical response. The duration of treatment for endocarditis should be 6 weeks, in addition to potential cardiothoracic surgery. In neutropenic patients, at least 14 days are necessary, and antibiotics should be continued until the absolute neutrophil count is equal to or greater than 500 cells/μL. Bacteremia in the neutropenic patient may necessitate prolonged treatment of 4 to 6 weeks of appropriate antibiotic treatment in the presence of endocarditis, deep-seated infection, septic thrombosis, or persistent bacteremia occurring more than 72 hours after removal of a catheter.[23]

Removal of an infected vascular catheter or another infected foreign device (urinary catheter, implant) is recommended to control device-related infection due to *P. aeruginosa*. Source control of an infection nidus (drainage of an abscess or empyema, excision of necrotic tissue) is also of paramount significance. If the source can be controlled, 7 to 10 days of antibiotic treatment is often adequate.

Treatment of Pulmonary Infection

Antibiotic Options

Patients with ventilator-associated pneumonia and health care–associated pneumonia due to *P. aeruginosa* may have isolates resistant to many antibiotics. Provided that renal and liver function is normal, empiric therapy can begin with double antipseudomonal coverage using (1) IV ceftazidime (2 g every 8 hours), cefepime (2 g every 8 to 12 hours), imipenem (500 mg every 6 hours or 1 g every 8 hours), meropenem (1 g every 8 hours), piperacillin-tazobactam (4.5 g every 6 hours) or aztreonam (2 g IV q 8 hours) plus a quinolone (levofloxacin 750 mg IV once daily or ciprofloxacin 400 mg IV every 8 hours) or an aminoglycoside (amikacin 15 to 20 mg/kg once daily, with a trough level of less than 4 to 5 μg/mL for amikacin, gentamicin 5 to 7 mg/kg IV every 24 h or tobramycin 5-7 mg/kg every 24 h) **or** a polymyxin. Dosing is based on colistin-based activity: 30 mg of colistin based activity (which corresponds to about 80 mg of the prodrug colistimethate) is 1 million international units. In the absence of other options, aztreonam is suggested as an adjunct to another β-lactam for the treatment of ventilator-associated pneumonia and for health care–associated pneumonia. Additional options include ceftazidime-avibactam (2 g of ceftazidime and 0.5 of avibactam infused over 2 hours when creatinine clearance is >50 mL/min, with modifications if it is lower); ceftolozane-tazobactam[A1] (3 g every 8 hours infused over 1 hour if the creatinine clearance is >50 mL/min, with modifications if it is lower); cefiderocol[A2] (2 g every 8 hours infused over 3 hours if the creatinine clearance is >60 mL/min, with modifications if it is lower); or imipenem-cilastatin-relebactam[A3] (500 mg + 500 mg + 250 mg every 6 hours infused over 30 minutes if clearance is 60 to 89 mL/min or higher and 0.75 g [imipenem 300 mg, cilastatin 300 mg, and relebactam 150 mg] if clearance is 30 to 59 mL/min, with modifications if it is lower). Doripenem is not recommended for pneumonia.

If patients with ventilator-associated pneumonia/health care-associated pneumonia due to *P. aeruginosa* are not in septic shock or at high risk for death and if the results of antibiotic susceptibility testing are known, current guidelines suggest switching to monotherapy. However, combination therapy should be continued for patients with shock or a high risk for death. A 7-day course of antibiotic therapy is the current recommendation for ventilator-associated and hospital-associated pneumonia, depending on the rate of improvement of clinical, radiologic, and laboratory parameters.

Cystic Fibrosis

Aminoglycosides are not optimally active in the lungs at concentrations used for intravenous administration, and oral ciprofloxacin (750 mg every 12 hours) is as good as intravenous therapy for patients with cystic fibrosis (Chapter 77).[A4] The administration of aerosolized aminoglycoside also may provide adequate drug levels in the tracheobronchial tree. Inhaled tobramycin (300 mg daily) and aztreonam lysine (75 mg three times daily for 28 days) are safe and efficacious for patients with cystic fibrosis.[A5] Inhaled colistin, which is also effective and safe in patients with cystic fibrosis, can be combined with an intravenous polymyxin (colistin or polymyxin B: see earlier) in patients without cystic fibrosis on a compassionate basis if the *P. aeruginosa* is susceptible only to polymyxins.

Endocarditis

Combination antibiotic therapy with an antipseudomonal β-lactam (antipseudomonal penicillin or cephalosporin or carbapenem [meropenem or imipenem]) and either an aminoglycoside or antipseudomonal fluoroquinolone for 6 weeks is suggested for the treatment of endocarditis. Surgery is required in a significant number of patients with *P. aeruginosa* left-sided endocarditis but hopefully can be avoided in right-sided endocarditis because the background of intravenous drug use will expose the patient to the subsequent risk of prosthetic valve endocarditis.

Meningitis/Brain Infection

Standard therapy to treat meningitis due to *P. aeruginosa* includes ceftazidime or cefepime. Alternative therapies are aztreonam, ciprofloxacin, and meropenem; the addition of aminoglycosides to these alternatives should be considered as well. The duration of treatment should be a total of 3 weeks or 2 weeks after the first sterile cerebrospinal fluid culture. Brain abscess and epidural and subdural empyema generally require surgical drainage in addition to antibiotics.

For shunt-related cerebrospinal fluid infections, removal of all components of the infected shunt plus appropriate antimicrobial therapy appears to be the most effective treatment. For patients with an infected shunt, the daily intraventricular dose is 1 to 8 mg for gentamicin, 5 to 20 mg for tobramycin, 5 to 50 mg (usually 30 mg) for amikacin, 5 mg for polymyxin B, and 10 mg for colistin. By comparison, the ventriculitis of the shunt infection appears to clear more rapidly with the drainage catheter still in place until the infection has cleared. Reshunting (placement of a new shunt) necessitates 10 to 14 days of sterile cerebrospinal fluid culture. Brain abscesses require an effort either to aspirate or drain them except if they are multiple, in difficult locations, of small size (less than 2.5 cm), or the patient has unacceptably high surgical risk. In addition, antibiotic treatment is needed for 6 weeks after adequate drainage and for 6 to 8 weeks if drainage is not performed.

Eye Infections

For keratitis, topical aminoglycosides or fluoroquinolones are recommended. If involvement is extensive, ceftazidime or gentamicin may be given by subconjunctival injection.

For endophthalmitis, therapy includes both systemic and intravitreal antibiotics. Ceftazidime has been the most frequently used antibiotic for this entity. Aminoglycosides are also injected subconjunctivally, by intraocular routes, and sometimes intravenously. Adjunctive surgery is generally performed to remove infected vitreous (vitrectomy).

Ear Infections

Acute otitis externa is treated with topical antibiotic agents (otic solutions), such as acetic acid (acetic acid 2% and acetic acid 2%/hydrocortisone 1%), aminoglycoside-containing otic solutions (neomycin plus polymyxin B and hydrocortisone), or quinolone-containing otic solutions (ciprofloxacin 0.2%/hydrocortisone 0.1%, ciprofloxacin 0.3%/dexamethasone 0.1% or ofloxacin 0.3%). Gentle removal of debris and cleaning with a mixture of acetic acid, alcohol, and distilled water may also help. The ear must be protected from scratching or mechanical injury. Chronically draining ears may require more intensive topical therapy.

Malignant external otitis requires débridement of the ear canal, including any necrotic tissue, cartilage, and adjacent bone. Antibiotic treatment with intravenous ciprofloxacin (usually 400 mg IV every 8 to 12 hours, but 750 mg orally every 12 hours if no cranial nerve involvement) or an antipseudomonal β-lactam (a cephalosporin such as ceftazidime or cefepime, carbapenem [meropenem or imipenem], or monobactam) dosed as for bacteremia is necessary for 6 to 8 weeks. Good glycemic control is very important for the resolution of the infection.

Urinary Tract Infection

The majority of *P. aeruginosa* urinary tract infections (Chapter 263) are complicated. Urinary catheters, stents, or stones should be removed if possible. In general, 7 to 10 days of antibiotic treatment will suffice, but up to 2 weeks is recommended for severe pyelonephritis. Abscesses (renal, perirenal) should be drained (especially if ≥3 cm), and a protracted course of antibiotics (4 to 6 weeks) should be administered. Quinolones (ciprofloxacin, 400 mg IV every 8 to 12 hours), levofloxacin (750 mg IV once daily), and aminoglycosides (e.g., amikacin at 15 mg/kg per 24 hours) have the pharmacodynamic advantage of excellent concentrations in the urinary tract. Antipseudomonal β-lactam/β-lactamase inhibitors (e.g., piperacillin-tazobactam 4.5 g every 8 hours) and carbapenems (e.g., doripenem at 500 mg IV [infusion over 1 hour] every 8 hours for 10 days) are equally acceptable, given their normally high levels of urinary excretion. Ceftazidime-avibactam 2 g of ceftazidime and 0.5 of avibactam, infused over 2 hours and administered every 8 hours, when creatinine clearance is >50 mL/min, with modifications if it is lower) and ceftolozane-tazobactam (1.5 g every 8 hours; half the dose suggested for pneumonia; infused over 1 hour if the creatinine clearance >50 mL/min, with modifications if it is lower) are other options. For difficult-to-treat *P. aeruginosa*, ceftazidime-avibactam,[A6] ceftolozane-tazobactam, imipenem-cilastatin-relebactam,[A7] and cefiderocol (as dosed for bacteremia) are first-line agents for cystitis, pyelonephritis, and complicated urinary tract infections. A single dose of aminoglycoside (e.g., amikacin 15 mg/kg every 24 hours) is also an option for cystitis. For pyelonephritis and complicated urinary tract infections, the alternative treatment suggested is once-daily aminoglycoside (e.g., amikacin 15 mg/kg every 24 hours).

Intra-abdominal Infections

For intra-abdominal infections, drainage of any abscess cavity is critical. Antibiotic options include the same treatments as for complicated urinary tract infections. For difficult-to-treat infections, ceftazidime-avibactam, ceftolozane-tazobactam,[A8] or imipenem-cilastatin-relebactam, in the same doses as noted earlier, are suggested as preferred treatment with cefiderocol as an alternative only if these antibiotics are not tolerated. For complicated intraabdominal infections, ceftazidime-avibactam (2.5 g every 8 hours) and ceftolozane-tazobactam (1.5 g every 8 hours) must be combined with metronidazole (loading dose 15 mg/kg infused over 1 hour, and maintenance dose 7.5 mg/kg infused over 1 hour every 6 hours) for anaerobic coverage. The duration of antibiotic treatment should be 7 to 10 days.

Skin Infections

Ecthyma gangrenosum is treated as for bacteremia. Burn wound infection requires extensive débridement of colonized eschar or necrotic tissue in addition to antibiotic treatment, which is as for bacteremia.

Hot tub folliculitis is usually self-limited; in difficult-to-resolve infections oral ciprofloxacin (500 mg twice daily for 7 days) is effective. For toe web infections, topical acetic acid (3 to 5%) compresses two to four times daily for 4 to 16 weeks is recommended. Concurrent treatment of tinea pedis (Chapter 405), if present, is necessary. If typical therapy fails, débridement of the onycholytic part of the nail and oral ciprofloxacin (500 mg twice daily for 7 days) are recommended. Topical polymyxins have also been used.

Bone Infection

Osteochondritis complicating puncture wounds of the foot requires intravenous antibiotics (cefepime, ceftazidime, or piperacillin-tazobactam) in the same doses as for bacteremia or oral ciprofloxacin (500 mg twice daily for 7 to 14 days) in addition to tissue biopsy and removal of necrotic cartilage.

Vertebral osteomyelitis requires surgical drainage in the presence of neurologic compromise, significant vertebral destruction with instability, a large epidural abscess, intractable back pain, or failure of medical treatment. Patients should receive a 6-week course of the following antibiotics: as first choice (adjusted for renal function) are cefepime (2 g IV every 8-12 hours) or meropenem (1 g IV every 8 hours) or doripenem (500 mg IV every 8 hours). Alternatives include ciprofloxacin (750 mg orally every 12 hours or 400 mg IV every 8 hours) or ceftazidime (2 g IV every 8 hours). For penicillin-allergic patients and quinolone-resistant strains, aztreonam (2 g IV every 8 hours) is suggested. Combination therapy with use of an antipseudomonal β-lactam plus ciprofloxacin or an antipseudomonal β-lactam plus an aminoglycoside can be considered when the disc space has been infected via hematogenous seeding.

For treatment of chronic osteomyelitis, oral ciprofloxacin (750 mg twice daily) for 6 to 12 weeks is acceptable as an alternative to parenteral treatment. Chronic osteomyelitis and sternoarticular osteomyelitis often require débridement of necrotic bone tissue. For prosthetic joint infection, removal of the prosthesis (two-stage exchange usually in the United States, but one-stage exchange has also been used) is usually required.

PREVENTION

Primary prevention includes preventing pollution of water by *Pseudomonas* in both the public and the hospital environments. Since outbreaks have been linked to whirlpools, swimming pools, and spas, proper antibacterial treatment of water is essential. Contamination of various equipment and devices (i.e., breast implants, ocular implants, and sinus irrigation devices) must be avoided. Handwashing is critical. Hospital point-of-use water filtration can be helpful. Barrier nursing practices may decrease horizontal transmission, especially in

the critical care environment. Isolation of patients infected with extensively drug-resistant and pandrug-resistant *P. aeruginosa* and strict infection control measures (dedicated personnel and equipment, use of gowns and gloves) may be needed to avoid intrahospital spread. Nevertheless, even antiseptic solutions may be contaminated by *P. aeruginosa*

PROGNOSIS

Even with treatment, mortality rates of 30% have been reported for *P. aeruginosa* bacteremia, pneumonia, bone infections, and CNS infections, with mortality rates twice as high when inappropriate antibiotics are used (usually for multidrug-resistant strains). Furthermore, *P. aeruginosa* infections are associated with increased length of hospitalization and medical costs. Loss of vision is the grave outcome of ophthalmic infection. Antibiotic resistance associated with *P. aeruginosa* will most likely continue to pose an enormous burden on human lives and financial resources in years to come.

Otitis externa usually resolves without sequelae, but it can cause drainage or progress to chronic suppurative otitis media, perichondritis, or acute mastoiditis.

BURKHOLDERIA INFECTIONS

Gram-negative bacillary members of the genus *Burkholderia* include *B. pseudomallei*, *B. mallei*, and *B. cepacia* complex (*B. cepacia* complex). *B. cepacia* and *B. pseudomallei* are motile, gram-negative, lactose nonfermenting bacteria, whereas *B. mallei* is nonmotile.

MELIODOSIS (*BURKHOLDERIA PSEUDOMALLEI*)

Melioidosis, which is an infection due to *Burkholderia pseudomallei*, occurs mainly in Southeast Asia and Australia,[24] (where its incidence is about 50/100,000 population), as well as in the Indian subcontinent and Sri Lanka. However, it also has been reported in Mexico, the northern part of South America, and Madagascar. More than three quarters of cases occur during the local rainy season. The portal of entry includes the respiratory system, the skin, and the gastrointestinal system, with intense inflammation with abscess formation and necrosis in the affected organs, such as the skin, liver, spleen, or lungs. Infection can also afflict immunocompetent travelers to the regions mentioned. Risk factors for acquisition of melioidosis include renal failure, diabetes mellitus, heavy alcohol consumption, chronic respiratory disease, thalassemia, glucocorticoid therapy, and cancer.

Clinical manifestations vary from asymptomatic infection to localized skin infection, pneumonia, and fulminant sepsis due to bacteremia.[25] The formation of abscesses is a usual feature of the disease. Other manifestations include septic arthritis, osteomyelitis, prostatitis, neurologic manifestations (e.g., brain stem encephalitis associated with cranial nerve palsies or myelitis with peripheral motor weakness), and kidney and spleen involvement. Suppurative parotitis, bilateral in 10% of cases, is seen in Thailand and Cambodia. The bacterium may remain dormant and then reactivate in approximately 75% of cases.

Culture remains the cornerstone of diagnosis. Serology and PCR have high specificities, but their current sensitivities are below 80%.[26]

TREATMENT

Bacteremia requires 10 to 14 days of intravenous ceftazidime (2 g every 8 hours), meropenem (1 g every 8 hours), or imipenem (1 g every 6 hours).[27] A switch from ceftazidime to meropenem is warranted if the patient develops organ failure or a new focus of infection, or if blood cultures remain positive after 1 week of treatment. In cases of ongoing septic shock, deep-seated or organ abscesses, extensive pulmonary disease, osteomyelitis, septic arthritis, or melioidosis with neurologic manifestations, parenteral treatment often must be continued for 4 or more weeks. After initial intravenous antibiotics, a 12-week course of oral eradication with trimethoprim/sulfamethoxazole (320 mg/1600 mg twice daily for patients weighing over 60 kg; 240 mg/1200 mg twice daily for patients weighing 40 to 60 kg) is required.[A9] Alternatives in the case of allergy or adverse events are amoxicillin-clavulanate (three 500/125-mg tablets three times daily for patients weighing 60 kg or more; two 500/125-mg tablets three times daily for patients weighing less than 60 kg)

B. pseudomallei is a bioterrorism factor B (Chapter 19), so appropriate infection control and notification of authorities are mandatory. Postexposure prophylaxis may be necessary for 3 weeks with trimethoprim/sulfamethoxazole or amoxicillin/clavulanate in the same doses as for oral eradication treatment.

GLANDERS (*BURKHOLDERIA MALLEI*)

Glanders is an equine infection due to *B. mallei*. Humans acquire the disease from contact with horses or, more rarely, donkeys or mules in an occupational setting. The disease has been eradicated in many countries, but cases can occur, especially in association with an occupational risk in veterinarians, veterinary students, farriers (hoof care workers), flayers (hide workers), transport workers, soldiers, slaughterhouse personnel, farmers, and horse fanciers. *B. mallei* remains a significant cause of zoonosis and is also a significant class B bioterrorism agent (Chapter 19).

The clinical manifestations are primarily tracheobronchitis, pneumonia, skin lesions, or lymphadenopathy.

DIAGNOSIS

Identification of the pathogen is based on culture of relevant biologic fluids. As an adjunct, PCR testing may be helpful.

TREATMENT

The approach to treatment is similar to melioidosis, with intravenous meropenem, imipenem, or ceftazidime initially and then oral trimethoprim-sulfamethoxazole for 3 to 12 months.

BURKHOLDERIA CEPACIA

B. cepacia is a plant and human pathogen. *B. cepacia* belongs to the *B. cepacia* complex, which includes also *B. ambifaria, B. anthina, B. arboris, B. cenocepacia, B. contaminans, B. diffusa, B. dolosa, B. latens, B. lata, B. metallica, B. multivorans, B. pseudomultivorans, B. pyrrocinia, B. seminalis, B. stabilis, B. stagnalis, B. territorii, B. ubonensis*, and *B. vietnamiensis*. *B. cenocepacia*, *B. multivorans*, and *B. cepacia* are the predominant species of the *B. cepacia* complex that infect mainly patients with cystic fibrosis (Chapter 77), chronic granulomatous disease (Chapter 153), sickle cell disease (Chapter 149), burns (Chapter 97), bronchiectasis (Chapter 78), or malignancy. However, *B. cenocepacia*, *B. multivorans*, and *B. cepacia* infections (and of other *B. cepacia* complex species) can infect hospitalized patients with central venous catheters, manipulation of the urogenital tract (catheterization, instrument insertion, and biopsy), burns, and wounds (surgical and other). In the hospital environment, outbreaks have been linked to aerosolized medications, chlorhexidine solutions, napkins, and prefabricated clothes.[28] Horizontal patient-to-patient transmission also occurs, with significant morbidity and mortality.

B. cepacia complex is implicated in infections of the lung, blood, and other sites in immunocompromised patients and even in immunocompetent patients. Patients with cystic fibrosis typically present initially with asymptomatic carriage but can develop pneumonia associated with a progressive decline of lung function. The most dramatic presentation is the cepacia syndrome, which is a fulminant necrotizing pneumonia often accompanied by bacteremia. Other manifestations include meningitis, endophthalmitis, pericarditis, endocarditis, burn wound infection, cholangitis, peritonitis, abscesses in the abdomen, perineum, or scrotum, and post-lung transplant pneumonia. Diagnosis is based on culture of relevant biologic fluids. PCR testing may also aid to expedite diagnosis.

TREATMENT

Trimethoprim-sulfamethoxazole (10 to 15 mg/kg/day based on trimethoprim component) is the first-line treatment, but some isolates are resistant to it. Other first-line options are meropenem (1 to 2 g every 8 hours) or ceftazidime (2 g every 8 hours). Minocycline (100 mg IV every 12 hours) is a second-line option. Ciprofloxacin, ticarcillin/clavulanate, and piperacillin/tazobactam can be used depending on sensitivity testing. In critically ill patients, especially with resistant species, combination antibiotic treatment may be required.

PROGNOSIS

Melioidosis is associated with a 14% mortality rate in Australia and up to 40% in Southeast Asia. Glanders is rare in humans, but mortality even with treatment is about 40 to 50%. *B. cepacia* has a predilection for patients with cystic fibrosis and often signals impaired overall prognosis in these patients. In patients who present with the cepacia syndrome, survival is unusual. Furthermore, *B. cepacia* adversely affects transplantation, and many transplant centers will not undertake transplantation when *B. cepacia* is present because of the grave prognosis associated with the infection in the post-transplantation period.

DISEASES CAUSED BY *ACINETOBACTER* AND *STENOTROPHOMONAS* SPECIES

KEITH S. KAYE AND ROBERT A. BONOMO

ACINETOBACTER SPP

DEFINITION

The Pathogen

Acinetobacter spp are gram-negative, aerobic, coccobacillary bacteria, which are generally non–lactose-fermenting, nonfastidious, catalase positive, oxidase negative, and nonmotile, though their description of being "nonmotile" is questioned. The Gram stain appearance of *Acinetobacter* spp is highly dependent on the life cycle. In the early growth phases, *Acinetobacter* spp appear rod shaped. In the stationary phase, they acquire a coccobacillary morphology. *A. baumannii* and other members of the *A. calcoaceticus-baumannii* (Acb) complex are the most common human pathogens[1] among the more than 70 validated *Acinetobacter* spp (see E-Table 283-1 for 30 representative species) and more than 20 species that are reported but unvalidated and unnamed.[2]

EPIDEMIOLOGY

Acinetobacter spp are present in food and water,[3] and they can colonize many body surfaces and cause infection in almost any organ system. In the United States, *Acinetobacter* species are a leading cause of ventilator-associated pneumonia. The majority of infections originally was observed only in critically ill, immunocompromised, or injured hosts in intensive care units (ICUs), but infections can occur in non-ICU patients and patients in long-term care settings.[4] *Acinetobacter* spp also can cause superinfections complicating the course of patients with severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2).[5] Since the coronavirus disease 2019 (COVID-19) pandemic, the U.S. Centers for Disease Control and Prevention (CDC) reported a 35% increase in hospital-based carbapenem-resistant *Acinetobacter* and a 78% increase in hospital-onset cases.[6]

For example, in tropical regions of China, Asia, Australia, and the South Pacific, *Acinetobacter* spp can account for more than 15% of cases of community-acquired pneumonia. The common comorbid conditions predisposing to community-acquired pneumonia due to *Acinetobacter* spp are mainly chronic obstructive pulmonary disease (Chapter 76), renal disease (Chapter 116), diabetes mellitus (Chapter 210), and alcohol use disorder. In Saudi Arabia, *Acinetobacter* is one of the most common pathogens associated with late-onset and recurrent ventilator-associated pneumonia.

Outbreaks of *A. baumannii* skin infections were common among U.S. military personnel in Iraq and Afghanistan. *Acinetobacter* infection also has become increasingly common among patients in burn units (Chapter 97), sometimes resulting in unit-wide outbreaks. The frequency of *Acinetobacter* infections is often greater in the summer than in other seasons.

PATHOBIOLOGY

Acinetobacter spp colonize the oropharynx and tracheostomy tubes in patients on ventilators, so it is not surprising that the upper respiratory tract is the most common site for infection. The main factors associated with health care–associated pneumonia due to *Acinetobacter* spp are mechanical ventilation, previous antibiotic exposure, ICU stay, surgery, and underlying pulmonary disease. In hospital environments, *Acinetobacter* spp can withstand drying (desiccation) and may even be transmitted by aerosol/respiratory droplet. Among the resistance genes found in *Acinetobacter* spp are a large collection of genes encoding β-lactamases, aminoglycoside-modifying enzymes, and many efflux pumps.[7]

CLINICAL MANIFESTATIONS

The most common infections are respiratory (pneumonia), blood stream (bacteremia), urinary tract, wound, skin and soft tissue, and burn infections; osteomyelitis secondary to trauma, and meningitis. *Acinetobacter* spp infections have few distinguishing features except, in some instances, skin manifestations.

Pneumonia

The two distinct syndromes associated with respiratory tract infection due to *Acinetobacter* are community-acquired pneumonia and health care–associated pneumonia (Chapter 85). Community-acquired pneumonia due to *Acinetobacter* species is associated with a high incidence of bacteremia, acute respiratory distress syndrome (Chapter 90), sepsis, and death, with mortality rates sometimes exceeding 50%. Rarely, community-acquired pneumonia due to *Acinetobacter* species can be manifested with consolidation and multiple lung abscesses.

More frequently, *Acinetobacter* spp are a cause of pneumonia in patients who have risk factors for antimicrobial resistant organisms, often manifested as ventilator-associated pneumonia (Chapter 85). Health care–associated pneumonia due to *Acinetobacter* largely resembles the clinical spectrum of gram-negative pneumonias (bilateral infiltrates, pleural effusion, cavitations, hypoxemia, and bacteremia). Most cases are in patients on ventilators.

Bacteremia

Blood stream infection due to *Acinetobacter* spp is often a consequence of infection of intravenous catheters (i.e., central line–associated blood stream infection) or is secondary to health care–associated pneumonia. Less commonly, wound infections can cause bacteremia. Infective endocarditis (Chapter 61) is uncommon, with about 40% of cases involving a prosthetic valve.[8]

Urinary Tract Infection

Urinary tract infections are only rarely caused by *Acinetobacter* spp. An indwelling bladder catheter is the major risk factor.

Wound, Burn, and Skin and Soft Tissue Infections

Traumatic or postoperative wounds, burns (Chapter 97), and skin and soft tissue infections are among the most common sites of *Acinetobacter* infections. Prior antibiotic use or devitalized tissues are predisposing factors. The spectrum of infection can range from cellulitis to necrotizing fasciitis.

Necrotizing skin and soft tissue infections with *A. baumannii* occur in hosts with underlying comorbidities (e.g., trauma, cirrhosis), especially associated with the use of central venous catheters and parenteral nutrition, *Acinetobacter* spp–associated skin infections can be manifested with a peau d'orange appearance, with overlying tiny vesicles (Fig. 283-1), and, when untreated, can progress to necrotizing infection with bullae (hemorrhagic and nonhemorrhagic). Concomitant bacteremia is common.

Osteomyelitis

Osteomyelitis due to *Acinetobacter* spp occurs as a complication of open fractures or exposed bone. Gross findings include purulence, necrotic tissue, or

ACINETOBACTER SPP

DEFINITION

The Pathogen

Acinetobacter spp are gram-negative, aerobic, coccobacillary bacteria, which are generally non–lactose-fermenting, nonfastidious, catalase positive, oxidase negative, and nonmotile, though their description of being "nonmotile" is questioned. The Gram stain appearance of *Acinetobacter* spp is highly dependent on the life cycle. In the early growth phases, *Acinetobacter* spp appear rod shaped. In the stationary phase, they acquire a coccobacillary morphology. *A. baumannii* and other members of the *A. calcoaceticus-baumannii* (Acb) complex are the most common human pathogens[1] among the more than 70 validated *Acinetobacter* spp (see E-Table 283-1 for 30 representative species) and more than 20 species that are reported but unvalidated and unnamed.[2]

EPIDEMIOLOGY

Acinetobacter spp are present in food and water,[3] and they can colonize many body surfaces and cause infection in almost any organ system. In the United States, *Acinetobacter* species are a leading cause of ventilator-associated pneumonia. The majority of infections originally was observed only in critically ill, immunocompromised, or injured hosts in intensive care units (ICUs), but infections can occur in non-ICU patients and patients in long-term care settings.[4] *Acinetobacter* spp also can cause superinfections complicating the course of patients with severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2).[5] Since the coronavirus disease 2019 (COVID-19) pandemic, the U.S. Centers for Disease Control and Prevention (CDC) reported a 35% increase in hospital-based carbapenem-resistant *Acinetobacter* and a 78% increase in hospital-onset cases.[6]

For example, in tropical regions of China, Asia, Australia, and the South Pacific, *Acinetobacter* spp can account for more than 15% of cases of community-acquired pneumonia. The common comorbid conditions predisposing to community-acquired pneumonia due to *Acinetobacter* spp are mainly chronic obstructive pulmonary disease (Chapter 76), renal disease (Chapter 116), diabetes mellitus (Chapter 210), and alcohol use disorder. In Saudi Arabia, *Acinetobacter* is one of the most common pathogens associated with late-onset and recurrent ventilator-associated pneumonia.

Outbreaks of *A. baumannii* skin infections were common among U.S. military personnel in Iraq and Afghanistan. *Acinetobacter* infection also has become increasingly common among patients in burn units (Chapter 97), sometimes resulting in unit-wide outbreaks. The frequency of *Acinetobacter* infections is often greater in the summer than in other seasons.

PATHOBIOLOGY

Acinetobacter spp colonize the oropharynx and tracheostomy tubes in patients on ventilators, so it is not surprising that the upper respiratory tract is the most common site for infection. The main factors associated with health care–associated pneumonia due to *Acinetobacter* spp are mechanical ventilation, previous antibiotic exposure, ICU stay, surgery, and underlying pulmonary disease. In hospital environments, *Acinetobacter* spp can withstand drying (desiccation) and may even be transmitted by aerosol/respiratory droplet. Among the resistance genes found in *Acinetobacter* spp are a large collection of genes encoding β-lactamases, aminoglycoside-modifying enzymes, and many efflux pumps.[7]

CLINICAL MANIFESTATIONS

The most common infections are respiratory (pneumonia), blood stream (bacteremia), urinary tract, wound, skin and soft tissue, and burn infections; osteomyelitis secondary to trauma, and meningitis. *Acinetobacter* spp infections have few distinguishing features except, in some instances, skin manifestations.

Pneumonia

The two distinct syndromes associated with respiratory tract infection due to *Acinetobacter* are community-acquired pneumonia and health care–associated pneumonia (Chapter 85). Community-acquired pneumonia due to *Acinetobacter* species is associated with a high incidence of bacteremia, acute respiratory distress syndrome (Chapter 90), sepsis, and death, with mortality rates sometimes exceeding 50%. Rarely, community-acquired pneumonia due to *Acinetobacter* species can be manifested with consolidation and multiple lung abscesses.

More frequently, *Acinetobacter* spp are a cause of pneumonia in patients who have risk factors for antimicrobial resistant organisms, often manifested as ventilator-associated pneumonia (Chapter 85). Health care–associated pneumonia due to *Acinetobacter* largely resembles the clinical spectrum of gram-negative pneumonias (bilateral infiltrates, pleural effusion, cavitations, hypoxemia, and bacteremia). Most cases are in patients on ventilators.

Bacteremia

Blood stream infection due to *Acinetobacter* spp is often a consequence of infection of intravenous catheters (i.e., central line–associated blood stream infection) or is secondary to health care–associated pneumonia. Less commonly, wound infections can cause bacteremia. Infective endocarditis (Chapter 61) is uncommon, with about 40% of cases involving a prosthetic valve.[8]

Urinary Tract Infection

Urinary tract infections are only rarely caused by *Acinetobacter* spp. An indwelling bladder catheter is the major risk factor.

Wound, Burn, and Skin and Soft Tissue Infections

Traumatic or postoperative wounds, burns (Chapter 97), and skin and soft tissue infections are among the most common sites of *Acinetobacter* infections. Prior antibiotic use or devitalized tissues are predisposing factors. The spectrum of infection can range from cellulitis to necrotizing fasciitis.

Necrotizing skin and soft tissue infections with *A. baumannii* occur in hosts with underlying comorbidities (e.g., trauma, cirrhosis), especially associated with the use of central venous catheters and parenteral nutrition, *Acinetobacter* spp–associated skin infections can be manifested with a peau d'orange appearance, with overlying tiny vesicles (Fig. 283-1), and, when untreated, can progress to necrotizing infection with bullae (hemorrhagic and nonhemorrhagic). Concomitant bacteremia is common.

Osteomyelitis

Osteomyelitis due to *Acinetobacter* spp occurs as a complication of open fractures or exposed bone. Gross findings include purulence, necrotic tissue, or

ABSTRACT

Acinetobacter and *Stenotrophomonas* spp are most frequently recovered from hospitalized patients, especially in intensive care units. These pathogens most commonly cause respiratory tract infections. Recovery of these pathogens from the respiratory tract does not equal infection—colonization occurs, particularly among patients who are mechanically ventilated. Antimicrobial resistance is commonly detected among both pathogens. Infections due to *Acinetobacter* spp are often treated with either sulbactam (given as ampicillin-sulbactam in the United States) or a carbapenem (meropenem or imipenem). Extremely drug-resistant (XDR) strains can be treated with minocycline, tigecycline, cefiderocol, or polymyxins. Combination therapy is often reserved to treat XDR *Acinetobacter* spp strains. For infections due to *Stenotrophomonas* spp, trimethoprim-sulfamethoxazole is considered the treatment of choice. Infection prevention is important in curtailing spread of these pathogens.

(From Guerrero DM, Perez F, Conger NG, et al. *Acinetobacter baumannii*–associated skin and soft tissue infections: recognizing a broadening spectrum of disease. *Surg Infect [Larchmt]*. 2010;11:49-57.)

environmental contamination. Fever higher than 38° C and leukocyte count greater than 12,000/μL are common, and *Acinetobacter* spp can be identified from culture of deep wound tissue obtained intraoperatively.

Meningitis

Acinetobacter is a very uncommon cause of meningitis in the community. *Acinetobacter* is occasionally a cause of hospital-acquired meningitis, particularly among patients with meningitis associated with an indwelling intraventricular catheter in the postoperative neurosurgical setting.

DIAGNOSIS

The classification and identification of the more than 70 different species in the genus *Acinetobacter* remain problematic. Diagnosis is usually assigned by culture, but polymerase chain reaction (PCR) arrays are now available for rapid typing and antibiotic genotypic susceptibility of the most common species. However, automated and biochemical systems are sometimes inaccurate.

TREATMENT

The major challenge complicating nosocomial pneumonia due to *Acinetobacter* species is the frequent recovery of multidrug resistant (MDR) and sometimes extensively drug resistant (XDR) strains. For skin infections, multiple drug resistance and the presence of co-pathogens frequently complicate treatment.

Antimicrobial Therapy

An increasing number of strains of *Acinetobacter* species are multidrug-resistant (MDR) or extremely drug-resistant (XDR) strains that are resistant to three or more classes of antibiotics, and in some cases, all antibiotics,[9] are often responsible for outbreaks in large hospitals. The emergence of strains of *Acinetobacter* that are resistant to carbapenems,[10] sulbactam, colistin, and polymyxin B leaves few treatment options, many of which need to be adjusted based on the degree of renal insufficiency with the aid of expert consultation.

When it is "susceptible," *Acinetobacter* is usually treated with sulbactam (ampicillin-sulbactam 3 g IV every 4 to 6 hours) or a carbapenem such as imipenem (500 to 1000 mg IV every 6 hours) or meropenem (500 to 1000 mg IV every 8 hours). Some experts recommend higher doses of meropenem (1 g IV every 6 hours or 2 g IV every 8 hours) and ampicillin-sulbactam (3 g IV every 4 hours over 4 hours).[11] Treatment is usually for 7 to 10 days for complicated urinary tract infection, 7 to 14 days for pneumonia and skin and soft tissue infections, 7 to 14 days for bacteremia, 21 days for meningitis (and longer if cerebrospinal fluid cultures remain positive), and 4 to 6 weeks for osteomyelitis. Susceptibility to imipenem does not always translate to susceptibility to meropenem. Aminoglycosides (e.g., amikacin 15 to 20 mg/kg then dose by therapeutic drug monitoring) are an option for treatment of urinary tract infection and potentially for systemic infections. The presence of methyl transferases limits the use of aminoglycosides, including plazomicin.

Treatment of infection with XDR *Acinetobacter* requires expert consultation, and many experts recommend combination therapy.[12] Tigecycline (100 to 200 mg loading dose, then 50 to 100 mg IV every 12 hours) and minocycline (200 mg IV or PO initially, followed by 100 to 200 mg IV or PO every 12 hours for 7 to 10 days) have good in vitro activity against many strains of XDR *Acinetobacter*. These agents are appropriate for treatment of skin and soft tissue infections, but monotherapy usually should be avoided, and combination therapy with at least 2 active agents is preferred. For example, initial therapy for invasive infections such as bacteremia and pneumonia might also include combination therapy with tigecycline or minocycline until clinical improvement is noted, with therapy then switched to single agent to complete the course of treatment. Sometimes, there is no choice but to use tigecycline as it might be the only available agent with in vitro activity against infecting *Acinetobacter* strains. Eravacycline (1 mg/kg IV every 12 hours), which is a new synthetic fluorocycline, may also be useful against *Acinetobacter* spp.

Cefiderocol, (3-hour IV infusion of 2 g every 8 hours) has excellent in vitro activity against *Acinetobacter* spp.[13] It appears to be equivalent to meropenem for the treatment of gram-negative pneumonia[A1] but inferior to other regimens for the treatment of invasive *Acinetobacter* spp infections.[A2]

Invasive infections due to XDR strains, such as bacteremia, pneumonia, and deep wound infections, are often treated with a polymyxin antimicrobial, either colistin or polymyxin B for 7 to 10 days. For colistin, a loading dose of 300 mg should be administered, followed by maintenance dosing of 150 to 180 mg every 12 hours, with subsequent dose adjustments made according to renal function.[14] If polymyxin B is used, a loading dose of 2.5 mg/kg × 1 should be administered intravenously, followed by a dose of 2.5 to 3.0 mg/kg/day in divided doses every 12 hours infused over a period of 60 minutes.[15] The major adverse effect of polymyxin therapy is nephrotoxicity.

Clinicians often treat invasive infections due to XDR *Acinetobacter* with combination therapy, despite a lack of randomized trial data demonstrating its superiority. Agents often combined with sulbactam[16] or polymyxin include imipenem or meropenem, sulbactam (ampicillin-sulbactam), tigecycline or minocycline, and aminoglycosides. Cefiderocol is another agent to consider in combination therapy. In controlled trials, however, neither rifampin nor meropenem added measurable clinical benefit over colistin monotherapy for the treatment of serious infection due to MDR or XDR *Acinetobacter*.[A3,A4] The role of combination therapy in preventing the emergence of polymyxin resistance during therapy remains uncertain.

For *Acinetobacter* meningitis, treatment should be intravenous meropenem (2000 mg every 8 hours) plus the intraventricular/intrathecal administration of an aminoglycoside (gentamicin [4 mg once daily every 1 to 3 days] or amikacin [30 mg once daily], if required, depending on susceptibilities), until clinical and microbiologic improvement occurs. For cases of meningitis due to XDR *Acinetobacter,* intravenous colistin or polymyxin B should be supplemented with intraventricular or intrathecal colistin (10 mg/day), or polymyxin B (5 to 10 mg/day). Other options to consider include high dose ampicillin-sulbactam and cefiderocol.

Surgical Therapy

Necrotizing skin infections require surgical débridement. Bone infections frequently require multiple surgical débridements of necrotic bone.

PREVENTION

Infection prevention practices, including hand hygiene, use of contact precautions, maintenance of environmental cleanliness, and implementation of antimicrobial stewardship, can help prevent spread of *Acinetobacter* in the hospital (Chapter 261).[A5] Removal of indwelling devices from patients, including vascular catheters and endotracheal tubes, can help prevent colonization and infection with *Acinetobacter*. However, the benefit of universal gloves and gowns is small if at all. During outbreaks, cohorting of patients and use of dedicated staff to care for cohorted patients can be necessary to control spread.

PROGNOSIS

Invasive infection due to *Acinetobacter* has been associated with crude mortality rates in excess of 50%, increases in duration of ICU stay of 6 days, and increases in duration of total hospital stay of more than 14 days. Furthermore, data indicate that infection is a cause of, not a marker of, poorer prognosis. In most series, mortality associated with blood stream infection ranges from approximately 15% to greater than 50%. *Acinetobacter*

meningitis in the neurologic setting has a mortality exceeding 15 to 30%. Fatal *A. baumannii* infections in relatively immunocompetent patients appear to be related to clade B. With appropriate early empirical therapy, however, the mortality rate for community-acquired infection can be as low as 11%.[17]

In general, infections due to more resistant strains of *Acinetobacter* are associated with less favorable outcomes than are infections due to more susceptible strains. These worse outcomes are likely due in part to limited and suboptimal treatment options as well as delays in the time to implementation of effective antimicrobial therapy for patients with infections due to MDR and XDR *Acinetobacter* strains.[18]

STENOTROPHOMONAS MALTOPHILIA

DEFINITION

S. maltophilia has attracted significant attention because it is often multidrug resistant due to intrinsic and acquired factors. *S. maltophilia* infection contributes significantly to morbidity, but usually not mortality, in immunocompromised patients.

The Pathogen

S. maltophilia are gram-negative bacteria that need methionine for growth and, like *Pseudomonas aeruginosa* and *Acinetobacter* spp, are non–lactose fermenters. *S. maltophilia* possess flagella that are multitrichous (more than one flagellum arising from the pole) and are distinguished from *P. aeruginosa* as oxidase negative. Colonies of *S. maltophilia* may appear pale yellow or lavender-green on blood agar plates. The organism emits a mild ammonia-like odor that is used for preliminary identification.

EPIDEMIOLOGY

S. maltophilia is an opportunistic global pathogen of environmental, mainly plant-associated origin. *S. maltophilia* can colonize and form biofilms on inanimate surfaces in the hospital, including catheters, intravenous fluid, water supplies, and hospital equipment.[19] This pathogen may also survive in hospital-grade disinfectant. Other health care–associated sources of *S. maltophilia* include contaminated intravenous fluids, hospital water and ice supplies, nebulizers, dialysis machines, ventilator circuits, thermometers, blood gas analyzers, intra-abdominal balloon pumps, and central venous or arterial pressure monitors.

A number of risk factors are associated with infection by *S. maltophilia* (Table 283-1). Although *S. maltophilia* is regarded as primarily a nosocomial pathogen (it is the third most common nonfermenting gram-negative bacillus health care–associated pathogen), community-acquired infection can occur. *S. maltophilia* infection primarily affects immunocompromised patients, including patients with hematologic malignancies; patients who have undergone solid organ transplantation; patients who are mechanically ventilated; hemodialysis patients with intravascular catheters; combat trauma patients; and patients with cystic fibrosis (Chapter 77).

The respiratory tract is the most common site of isolation of *S. maltophilia* in the hospital. Surveillance programs report a rate of culture-positivity of *S. maltophilia* from hospitalized patients with pneumonia of more than 3% in the United States.

TABLE 283-1 RISK FACTORS FOR INFECTION BY *STENOTROPHOMONAS MALTOPHILIA*

Prolonged hospitalization or intensive care unit stay
Intravascular catheters
Indwelling devices
Mechanical ventilation or tracheostomy
Neutropenia or cytotoxic chemotherapy
Solid organ transplantation
Immunocompromised state
Mucositis
Malignant disease
Chronic lung disease (especially cystic fibrosis and chronic obstructive pulmonary disease)
Human immunodeficiency virus infection
Hemodialysis
Antibiotic exposure (especially to carbapenems, extended-spectrum cephalosporins, and fluoroquinolones)
Exposure to other patients with *S. maltophilia*

PATHOBIOLOGY

Isolates are generally genotypically and phenotypically diverse. However, there is phylogenetic clustering, and recent studies have demonstrated the predominance of strains belonging to the lineage Sm6 (former genomic group 6) causing human infections.[20] The association of Sm6 with antibiotic resistance and virulence genes points towards a potential adaptation of this lineage to human infection and enhanced virulence.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Respiratory Tract

S. maltophilia is frequently isolated from pulmonary aspirations in patients who are on mechanical ventilators, have tracheostomy tubes in place, or are receiving broad-spectrum antibiotics, including about 3% of patients who are hospitalized with pneumonia.[21] Nosocomial pneumonia due to *S. maltophilia* is often associated with significant underlying pulmonary disease, such as emphysema (Chapter 76), bronchiectasis (Chapter 78), cystic fibrosis (Chapter 77), lung transplantation, or endobronchial obstruction (Chapter 87). Among mechanically ventilated patients, it can be challenging to differentiate *S. maltophilia* colonization from infection.

Community-acquired pneumonia due to *S. maltophilia* has been reported but is very rare. In cystic fibrosis (Chapter 77), infection often occurs when patients develop resistance to antipseudomonal antibiotics.

Blood Stream Infection and Endocarditis

Bacteremia may be secondary to a respiratory, urinary, or gastrointestinal source but is most commonly due to infection of an indwelling intravascular device. In many cases, except for those involving intravenous catheters, the portal of entry is not apparent. Immunocompromised patients are at particularly high risk. Intravenous drug users are at especially high risk for contaminating prosthetic valves with S. *maltophilia*.

Other Sites of Infection

Although *S. maltophilia* is frequently recovered from urine specimens in patients with indwelling urinary catheters, the role of this organism as a pathogen in this setting is unclear. Central nervous system infections due to *S. maltophilia* are rare, and typically associated with central nervous system devices or antecedent neurosurgery.[22]

S. maltophilia can be isolated from postoperative wounds, but its role as a pathogen in this setting is unclear. In contrast, *S. maltophilia* can cause burn wound sepsis (Chapter 97), manifested as a syndrome very similar to ecthyma gangrenosum (Chapter 408) in immunocompromised oncology patients.

TREATMENT

S. maltophilia exhibits intrinsic resistance to many antibiotics,[23] including imipenem, piperacillin-tazobactam, ceftazidime, and aminoglycosides (Table 283-2). Various combination regimens for invasive *S. maltophilia* infections have been studied, but their efficacy in clinical settings remains unclear. Inhaled antibiotics are a therapeutic option for cystic fibrosis, but their clinical effectiveness remains unknown.

Trimethoprim-sulfamethoxazole (10 to 15 mg/kg/day IV, based on the trimethoprim component) is the drug of choice. Treatment duration is uncertain; it is usually 7 to 14 days but might be longer for deep-seated or endovascular infections. Resistance to trimethoprim-sulfamethoxazole has become more common, particularly in patients with cystic fibrosis (Chapter 77). In these cases, minocycline (200 mg followed by 100 to 200 mg every 12 hours, not to exceed 400 mg in 24 hours), some of the fluoroquinolones (particularly levofloxacin 750 mg every 24 hours and moxifloxacin 400 mg every 24 hours), and tigecycline (200 mg loading dose then 100 mg every 12 hours) may be useful agents. Cefiderocol (3-hour IV infusion of 2 g every 8 hours) has good in vitro activity and is a promising agent, but clinical experience is limited. Polymyxin-based regimens may serve as alternatives in the face of resistance to trimethoprim-sulfamethoxazole, but susceptibility should be confirmed prior to administration. Polymyxin B has greater in vitro activity than colistin (see earlier for details regarding polymyxin treatment). The addition of the β-lactam/β-lactamase inhibitor combination ceftazidime-avibactam to aztreonam can preserve aztreonam activity in the setting of β-lactamase production. For moderate to severe infections, some experts recommend combination therapy, such as trimethoprim-sulfamethoxazole plus minocycline.

For blood stream infections, removal of any infected device is an important component of management. In the case of endocarditis, favorable outcomes are reported with antimicrobial therapy, but surgery may also be required.

TABLE 283-2 MECHANISMS OF RESISTANCE IN *STENOTROPHOMONAS MALTOPHILIA*

DRUG	MECHANISM OF RESISTANCE
β-Lactams, including imipenem	L1 and L2 β-lactamases Outer membrane permeability/efflux
Aminoglycosides	Aminoglycoside-modifying enzymes, transport
Ceftazidime	Efflux pump SmeH

PROGNOSIS

Among patients with ventilator-associated pneumonia or bacteremia due to *S. maltophilia*, overall mortality rates are in the range of 60%, with an attributable mortality due to invasive *S. maltophilia* infection of 12 to 38%. Patients who receive early appropriate antibiotic therapy appear to do better. Bacteremia is associated with poor outcomes, particularly in patients with malignancy or severe immunocompromising conditions.

In patients with cystic fibrosis (Chapter 77), *S. maltophilia* infection is associated with increases in exacerbations, a decline in lung function, hospitalization, need for lung transplantation, and mortality. Whether *S. maltophilia* has a causative association with these poor outcomes or is merely a marker for severe underlying disease is less clear.[24]

PREVENTION

Standard infection control practices, including hand hygiene and thorough environmental cleaning, can help prevent spread of *Stenotrophomonas* in the hospital (Chapter 261). In outbreak settings, contact precautions and possibly cohorting of patients have been used to control spread.

284 *SALMONELLA* INFECTIONS (INCLUDING ENTERIC FEVER)

JOHN A. CRUMP

DEFINITION

Many of the more than 2500 serovars (also called serotypes) of *Salmonella enterica* subspecies *enterica* infect humans and cause a range of clinical conditions from asymptomatic intestinal carriage to intestinal infection to invasive disease with extraintestinal complications.[1] Each serovar designation follows the species name (e.g., *Salmonella enterica* subspecies *enterica* serovar Typhimurium) and is frequently abbreviated as simply *Salmonella* followed by the serovar name (e.g., *Salmonella* Typhimurium).

The Pathogen

Members of the order Enterobacterales (also see Chapter 281), salmonellae are gram-negative, non-spore-forming bacilli. They can be differentiated into more than 2500 serovars by their somatic (O) antigens, which are composed of lipopolysaccharides and are part of the cell wall, and by their flagellar (H) and capsular (Vi) antigens. *Salmonella* serogroups were traditionally designated by letters based on O antigens (e.g., A, B, C1, C2). The growing number of serogroups then made it necessary to move to a numeric designation (e.g., O:2, O:4, O:6,7, O:8). Some of the important serovars and their serogroups are Typhi (group O:9), Choleraesuis (group O:7), Typhimurium (group O:4), and Enteritidis (group O:9). *Salmonella* Enteritidis and Typhimurium are the most common nontyphoidal serovars that cause human disease. Today, serovar can be inferred by whole genome sequencing, and subdivision within serovars, useful for epidemiologic investigations, is usually achieved by molecular or genomic subtyping methods.

EPIDEMIOLOGY

Salmonella Typhi, *Salmonella* Paratyphi A, *Salmonella* Paratyphi B, *Salmonella* Paratyphi C, and *Salmonella* Sendai are either solely or almost exclusively pathogens of humans; they cause primarily enteric fever rather than diarrhea, and transmission is usually through water or food. As a result of modern sewage and water treatment facilities, as well as improved food safety practices, typhoid fever and paratyphoid fever have become rare in high-income countries, but they remain a problem in countries that lack adequate sanitation and a safe water supply. Fewer than 500 cases of typhoid fever are usually reported annually in the United States, and most of those infections were acquired abroad. In contrast, an estimated 10.9 million typhoid illnesses occurred globally in 2017 and caused more than 135,000 deaths.[2,3] Nontyphoidal *Salmonella* serovars are a leading cause of community-onset bloodstream infection in sub-Saharan Africa, where children younger than 3 years and HIV-infected adults carry most of the burden of invasive disease.

Other serovars of *Salmonella* (described here as nontyphoidal *Salmonella*) have reservoirs in warm-blooded animals and cause human illness after the consumption of contaminated meat or animal products, contamination of produce or water by animal feces or animal products, or exposure to animals and their environments. Some nontyphoidal *Salmonella* serovars appear frequently in particular animal species, and about 10% of *Salmonella* infections may be attributable to animal exposure, including small pet turtles. *Salmonella* Enteritidis has a reservoir in chickens, and infection is often linked to the consumption of undercooked eggs and poultry products or to exposure to live chicks. Such a relationship is less clear for some other nontyphoidal serovars (e.g., *Salmonella* Typhimurium). Foodborne nontyphoidal *Salmonella* is estimated to be associated with approximately 1 million domestically acquired illnesses and about 450 deaths annually in the United States, and it is the leading cause of foodborne outbreaks of enterocolitis in the European Union.[4] In the United States, a disproportionate number of infections occur in July through October, probably related to warm weather. *Salmonella* infections are most common among infants and children younger than 5 years of age. Worldwide, nontyphoidal *Salmonella* causes an estimated 150 million illnesses and 50,000 to 60,000 deaths per year, with about 50% of these estimated to be foodborne.

Salmonellae are transmitted by the ingestion of fecally contaminated food or water; contact with animals, their environments, and other fomites; and, rarely, close contact with infected persons (e.g., oral-anal intercourse). The ultimate sources of contamination are humans or animals that are acutely ill or are shedding the organism without symptoms.

Contaminated Animal Products

Nontyphoidal *Salmonella* infection in humans usually occurs from ingestion of contaminated animal food products, most often eggs, poultry, and meat. *Salmonella* Choleraesuis is associated with pig products, *Salmonella* Dublin with cattle and unpasteurized milk from cattle, and *Salmonella* Enteritidis with poultry and poultry products, including eggs. Fecal material on poultry and other animal carcasses can spread at slaughterhouses, such as when many poultry carcasses are placed in the same hot-water tank to remove feathers. *Salmonella* that is contaminating carcasses can multiply to high levels if meat or other animal products are not refrigerated. Human illness may result if such animal products are inadequately cooked or if utensils or other uncooked foods are cross-contaminated during preparation. A wide range of foods can be contaminated with animal or human feces, from production on the farm through consumption in the home. Reports of produce-associated *Salmonella* outbreaks, due to contamination by animal or human feces during production,

TABLE 283-2 MECHANISMS OF RESISTANCE IN *STENOTROPHOMONAS MALTOPHILIA*

DRUG	MECHANISM OF RESISTANCE
β-Lactams, including imipenem	L1 and L2 β-lactamases Outer membrane permeability/efflux
Aminoglycosides	Aminoglycoside-modifying enzymes, transport
Ceftazidime	Efflux pump SmeH

PROGNOSIS

Among patients with ventilator-associated pneumonia or bacteremia due to *S. maltophilia*, overall mortality rates are in the range of 60%, with an attributable mortality due to invasive *S. maltophilia* infection of 12 to 38%. Patients who receive early appropriate antibiotic therapy appear to do better. Bacteremia is associated with poor outcomes, particularly in patients with malignancy or severe immunocompromising conditions.

In patients with cystic fibrosis (Chapter 77), *S. maltophilia* infection is associated with increases in exacerbations, a decline in lung function, hospitalization, need for lung transplantation, and mortality. Whether *S. maltophilia* has a causative association with these poor outcomes or is merely a marker for severe underlying disease is less clear.[24]

PREVENTION

Standard infection control practices, including hand hygiene and thorough environmental cleaning, can help prevent spread of *Stenotrophomonas* in the hospital (Chapter 261). In outbreak settings, contact precautions and possibly cohorting of patients have been used to control spread.

ABSTRACT

Salmonella Typhi, *Salmonella* Paratyphi A, *Salmonella* Paratyphi B, *Salmonella* Paratyphi C, and *Salmonella* Sendai are either solely or almost exclusively pathogens of humans; they cause primarily enteric fever rather than diarrhea, and transmission is usually through water or food. Other serovars of *Salmonella*, described here as nontyphoidal *Salmonella*, have reservoirs in warm-blooded animals and cause human illness after the consumption of contaminated meat or animal products, contamination of produce or water by animal feces or animal products, or exposure to contaminated animals and their environments. Although diarrhea due to nontyphoidal *Salmonella* is usually managed symptomatically, enteric fever and invasive nontyphoidal *Salmonella* disease require timely and appropriate antimicrobials. However, antimicrobial resistance is a growing problem among *Salmonella*, and resistance to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole is widespread. Resistance to azithromycin, fluroquinolones, and extended-spectrum cephalosporins is emerging. Vaccines are available to prevent typhoid fever, and prevention efforts for *Salmonella* infections focus on the provision of safe water and food.

are increasing. *Salmonella* outbreaks have occurred from contaminated cheese, ice cream, vegetables, fruit, juice, and alfalfa sprouts.

Contaminated Food and Water

Nontyphoidal *Salmonella* infections may be acquired after contamination of food or water with the feces of pet reptiles, turtles, chicks, ducks, birds, dogs, cats, and many other species. *Salmonella* infection can also be acquired by eating food or by drinking water contaminated by human fecal shedders who have not adequately washed their hands. Infection has been spread by the fecal-oral route among children, by contaminated enema and fiberoptic instruments, by diagnostic and therapeutic preparations made from animal or insect products (e.g., pancreatic extract, carmine dye), and from intentional or unintentional contamination of restaurant salad bars.

Contact with Animals and Their Environments

Both healthy and sick animals may harbor and shed *Salmonella*. Transmission of *Salmonella* from animals and their environment to humans occurs primarily by the fecal-oral route. Animal hides and saliva often harbor fecal organisms, and transmission can occur when persons pet, touch, feed, or are licked by animals. Transmission has also been associated with contaminated animal bedding, flooring, barriers, other environmental surfaces, and clothing and shoes. Contact with calves, turtles and other reptiles, rodents, and young poultry and their environments has been associated with *Salmonella* outbreaks.

Contact with Infected Persons

Close contact with persons shedding *Salmonella* is an occasional source of infection. Transmission has been documented among persons handling feces (e.g., parents changing the diapers of an infected infant) and is associated with certain sexual practices (e.g., oral-anal intercourse).

Antimicrobial Resistance

Salmonellae have become increasingly resistant to antimicrobial agents, often by acquiring resistance transfer factors (e.g., plasmid mediated). Mutations in the *waaY*, *phoP*, and *pmrB* genes also confer resistance to antimicrobial peptides. Antimicrobial resistance in the human-restricted salmonellae (e.g., *Salmonella* Typhi) is likely driven primarily by antimicrobial use in humans, whereas antimicrobial resistance among the nontyphoidal salmonellae (e.g., *Salmonella* Typhimurium) may be associated with the use of antimicrobial agents in farm animals. Among *Salmonella* Typhi recently isolated in the United States, about 80% were resistant or intermediate to ciprofloxacin, 12% were multiple drug resistant (i.e., resistant to the traditional first-line antimicrobials ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole), and 4% were extensively drug resistant (i.e., resistant to ampicillin, ceftriaxone, chloramphenicol, ciprofloxacin, and trimethoprim-sulfamethoxazole).[5] In Asia, about one-third of *Salmonella* Typhi are multidrug resistant, including about 8% resistant to azithromycin, and about 6% are resistant to third-generation cephalosporins. Resistance to third-generation spectrum cephalosporins remains rare among *Salmonella* Paratyphi A. Among human nontyphoidal *Salmonella* bloodstream isolates in the United States, resistance to three or more antimicrobial classes is common. In addition, about 5.0% of human nontyphoidal *Salmonella* bloodstream isolates are resistant to ceftriaxone and 4.5% are resistant to ciprofloxacin.

PATHOBIOLOGY

After the ingestion of organisms, the likelihood for developing infection, as well as the severity of infection, is related to the dose, the virulence of the *Salmonella* strain, and the status of host defense mechanisms. Usually at least 10^2 to 10^3 bacteria are required to produce clinical infection in a normal host. Higher inocula are associated with more severe disease, whereas smaller inocula are more likely to result in transient intestinal carriage. Gastric acid serves as a host defense mechanism by killing many of the ingested organisms, and intestinal motility is probably another host defense mechanism. In the absence of or with a decrease in gastric acidity (e.g., in infants and the elderly; after gastrectomy, vagotomy, or gastroenterostomy; or with the use of drugs that reduce gastric acidity) and with decreased intestinal motility (e.g., the use of antimotility drugs), much smaller inocula can produce infection, and the infection tends to be more severe. Administration of antimicrobial agents before the ingestion of salmonellae can markedly reduce the size of the inoculum needed to produce infection, presumably by reducing the concentration of protective bowel flora.

To produce infection, invasion must occur across the mucosa of the intestine. When the organisms reach the lamina propria, an influx of polymorphonuclear leukocytes serves as a host defense mechanism to prevent invasion of the lymphatics. Certain serovars seem to have a greater ability than others to invade the lymphatics and subsequently to produce bacteremia (e.g., *Salmonella* Choleraesuis and *Salmonella* Dublin, which commonly produce bacteremia after intestinal infection). Both the small intestine and the colon are involved in the inflammatory process.

In the case of *Salmonella* Typhi and other causes of enteric fever, salmonellae invade the mononuclear phagocytes in Peyer patches in the ileum and mesenteric lymph nodes. Some intracellular salmonellae form a nonreplicating population of "persisters" that can provide a reservoir for relapsing infection; intracellular persistence is determined by conditions in the vacuolar environment of the infected cells. Other organisms multiply intracellularly and are carried through the lymphatic system and blood stream to the liver, spleen, bone marrow, and other parts of the reticuloendothelial system. When in the reticuloendothelial system, organisms multiply intracellularly in mononuclear phagocytes and produce the systemic manifestations of enteric fever. The onset of fever is associated with bacteremia and the release of cytokines (e.g., tumor necrosis factor and interleukins) from mononuclear phagocytes. Ulcerations over Peyer patches are responsible for the intestinal manifestations of enteric fever, such as pain, perforation, and bleeding.

In *Salmonella* enterocolitis, the organisms remain localized in the intestinal mucosa, and diarrhea results from the inflammation produced by polymorphonuclear leukocytes. In addition, watery diarrhea may occur, apparently the result of the secretion of water and electrolytes by small intestinal epithelial cells in response to an enterotoxin secreted by some of the *Salmonella* strains or in response to tissue mediators of inflammation.

CLINICAL MANIFESTATIONS

Although any *Salmonella* serovar can produce any of the *Salmonella* syndromes (transient asymptomatic carrier state, enterocolitis, enteric fever, bacteremia, and chronic carrier state), each serovar tends to be associated with certain syndromes much more frequently than with others. For example, *Salmonella* Anatum usually causes asymptomatic intestinal infection, whereas *Salmonella* Typhimurium generally causes enterocolitis. *Salmonella* Choleraesuis is more likely to produce bacteremia (often with metastatic infection) than asymptomatic infection or enterocolitis, and some serovars such as *Salmonella* Typhi and *Salmonella* Paratyphi A[6] are most likely to cause enteric fever as well as the chronic carrier state. Fortunately, most *Salmonella* serovars are of relatively low pathogenicity for humans. Therefore, although food products are commonly contaminated, large outbreaks tend to involve the more virulent serovars.

Patients with diseases that impair host defense mechanisms seem to have an increased frequency of severe *Salmonella* infection. A striking association has been recognized between diseases producing hemolysis and *Salmonella* bacteremia. Specifically, *Salmonella* bacteremia is common in patients with sickle cell disorders (Chapter 149), malaria (Chapter 316), and bartonellosis (Chapter 291). In fact, because of the frequency of *Salmonella* bacteremia in sickle cell diseases and the underlying bone disease in these patients to which salmonellae localize, these organisms are the most common cause of osteomyelitis (Chapter 251) in patients with sickle cell disorders (Chapter 149). Prolonged *Salmonella* bacteremia may occur in patients with hepatosplenic schistosomiasis (Chapter 326), possibly related to localization on and in the intravascular schistosomes. Patients with lymphoma and leukemia (Chapters 168 to 172), are also more prone to the development of *Salmonella* bacteremia. A markedly increased frequency and severity of *Salmonella* infections in general have been observed in patients with human immunodeficiency virus (HIV) infection (Chapter 358), particularly those with $CD4^+$ T-lymphocyte counts less than 200 cells/μL. Prolonged and recurrent, refractory *Salmonella* bacteremia is common among these patients. Other risk factors that increase the frequency and severity of *Salmonella* infection are extremes of age, immunocompromised states (e.g., from immunosuppressive agents), malnutrition (Chapter 198), and probably diabetes (Chapter 210).

Asymptomatic Intestinal Carrier State

The asymptomatic intestinal carrier state may result from inapparent infection (which is the most common form of *Salmonella* infection), or it may follow clinical disease (in which case the patient becomes a convalescent carrier). The carrier state is usually self-limited to several weeks to months, with the prevalence of positive stool cultures rapidly decreasing over time. By 1 year, far less than 1% of carriers still have positive stools. The main exception is *Salmonella* Typhi, which about 3% of infected individuals excrete for life.

Women and older men are more likely to become chronic carriers, likely related to underlying abnormalities in their biliary tracts (Chapter 141). For example, a patient who has had salmonellae in the stool for 1 year (chronic carrier) is likely to become a lifelong carrier, with the reservoir in the biliary tree, usually in calculi in the gallbladder. Patients with *Schistosoma haematobium* (Chapter 326) infection also are predisposed to become chronic urinary carriers of salmonellae.

Enterocolitis

After an incubation period of usually 12 to 48 hours, the illness starts suddenly with crampy abdominal pain and diarrhea. Nausea and vomiting may occur but are usually not prominent or persistent. The diarrhea may be watery and of large or small volume. Stools may contain mucus and are occasionally bloody. Polymorphonuclear leukocytes are present in the stool. Diarrhea may be mild or severe, with up to 20 to 30 stools a day. Fever is present in most patients, and the temperature may reach 40° C (104° F) or higher. The abdomen is tender to palpation. Transient bacteremia may occur and is most commonly seen in infants, the elderly, and patients with impaired host defense mechanisms.

Symptoms generally improve during a period of fever persisting for no more than 2 to 3 days and diarrhea persisting for no more than 5 to 7 days. However, these symptoms occasionally persist for up to 14 days. More severe disease is seen with malnutrition (Chapter 198), inflammatory bowel disease (Chapter 127), and HIV infection (Chapter 358). Older patients are less likely to have bloody diarrhea but more likely to have severe illness requiring hospitalization.[7] Reactive arthritis (Chapter 254) may follow enterocolitis in up to 7% of cases, especially among patients who are HLA-B27 positive.

Enteric Fever

Enteric fever is produced by *Salmonella* Typhi (typhoid fever); *Salmonella* Paratyphi A, B, and C (paratyphoid fever)[8]; and occasionally other serovars. Sometimes it immediately follows classic enterocolitis caused by the same organism. In untreated disease, an incubation period of 5 to 21 days (generally 7 to 14 days) is followed by fever and malaise, often associated with cough. A small proportion of patients may have diarrhea during the incubation period. The fever tends to rise in a stepwise fashion during the first few days to a week and then becomes sustained, usually at 39.4° to 40.0° C (103° to 104° F) or higher. Relative bradycardia is seen in up to half of patients. Apathy, confusion, delirium, and even psychosis may occur. Abdominal distention, pain, and tenderness may occur in the first week and may be associated with diarrhea or constipation; these symptoms are generally more pronounced during the second week of fever. Most patients have abdominal tenderness during the course of the illness.

In about 30% of untreated light-skinned patients, but rarely in patients with darker skin, rose spots become visible on the abdomen or chest (or both) toward the end of the first week or during the second week of fever. These faint, salmon-colored maculopapular lesions are subtle and may be difficult to see, particularly in dark-skinned patients. Salmonellae can be cultured from punch biopsies of these lesions. Hepatosplenomegaly occurs in about half of patients. Leukopenia and neutropenia are seen in about 20%. Abnormal liver function test results are common.

After 2 weeks of untreated illness, the severe complications of intestinal hemorrhage and perforation related to necrosis of Peyer patches may be observed in about 5% of patients.

Rarely, patients may develop pancreatitis (Chapter 130), cholecystitis (Chapter 141), infective endocarditis (Chapter 61), meningitis (Chapter 381), pneumonia (Chapter 85), hepatic or splenic abscess (Chapter 137), orchitis, or focal infection at virtually any site. The illness usually resolves by the end of the fourth week in an untreated patient. Relapse may occur in untreated as well as in treated patients, but the illness is milder than the original episode.

Bacteremia

Patients with *Salmonella* bacteremia usually complain of fever and chills that persist for days to weeks. Gastrointestinal symptoms are unusual, but *Salmonella* bacteremia occasionally follows classic enterocolitis. Other symptoms are nonspecific, such as malaise, anorexia, and weight loss. Metastatic infection of bones, joints, aneurysms (particularly of the abdominal aorta), meninges (mainly in infants), pericardium, pleural space, lungs, heart valves, cysts, uterine myomas, malignant neoplasms, and other sites is common, and symptoms may be related to the site of metastatic infection. Stool cultures are often negative for salmonellae, but blood cultures are positive.

Although any *Salmonella* serovar can produce bacteremia, *Salmonella* Dublin, *Salmonella* Choleraesuis, *Salmonella* Heidelberg, *Salmonella* Oranienburg, *Salmonella* Panama, and *Salmonella* Sandiego are associated with increased likelihood of bacteremia.[9] *Salmonella* bacteremia occurs with increased frequency in infants, the elderly, and patients with diseases associated with hemolysis (e.g., sickle cell diseases, malaria, bartonellosis), HIV infection, lymphoma, leukemia, disseminated histoplasmosis, and perhaps systemic lupus erythematosus.[10] Localization to bone is common in patients with sickle cell diseases (Chapter 149), but osteomyelitis also can occur in immunocompetent patients without any risk factors.[11] In Africa, the common symptoms of invasive nontyphoidal *Salmonella* disease, which is seen predominantly in patients with HIV infection, malaria, and malnutrition, are fever, hepatosplenomegaly, and respiratory symptoms; features of enterocolitis are often absent.

Prolonged *Salmonella* bacteremia lasting for months may occur in patients with hepatosplenic schistosomiasis (Chapter 326). In patients with HIV infection, recurrent, relapsing *Salmonella* bacteremia may develop, which may be difficult to cure with antimicrobial agents.

DIAGNOSIS

Enterocolitis

Polymerase chain reaction (PCR) testing of stool specimens can provide accurate and rapid diagnosis.[12] When culture-independent diagnostic testing is positive for *Salmonella*, a definitive culture is still needed to yield an isolate for public health purposes. However, by the time the results of stool culture are available, most patients are recovering. A stained smear of the stool usually demonstrates polymorphonuclear leukocytes.

Although *Salmonella* enterocolitis is an invasive disease, the differential diagnosis includes all causes of acute diarrhea, including invasive bacteria such as *Campylobacter jejuni* (Chapter 279), *Shigella* species (Chapter 285), invasive *Escherichia coli* (Chapter 280), *Yersinia enterocolitica* (Chapter 288), and *Vibrio parahaemolyticus* (Chapter 278); toxigenic bacteria such as *Vibrio cholerae* (Chapter 278), enterotoxigenic *E. coli*, enterohemorrhagic *E. coli* (e.g., *E. coli* O157:H7; Chapter 280), *Staphylococcus aureus* (Chapter 267), *Bacillus cereus* (Chapter 272), *Clostridium perfringens* (Chapter 271), and *Clostridioides difficile* (Chapter 271); viruses (Chapters 349 and 350); and protozoa such as *Entamoeba histolytica* (Chapter 323), *Giardia intestinalis* (Chapter 322), and *Cryptosporidium* species (Chapter 321). The invasive bacterial causes of diarrhea, enterohemorrhagic *E. coli* and *C. difficile* infection, are also associated with polymorphonuclear leukocytes in stool, whereas bacterial toxigenic causes (other than *C. difficile* and enterohemorrhagic *E. coli*), viruses, and protozoa generally are not. The bacterial toxigenic causes of diarrhea other than *C. difficile* and enterohemorrhagic *E. coli* do not produce fever.

Bacteremia and Enteric Fever

The diagnosis of enteric fever is best proved by isolation of the microorganism from blood or bone marrow. Stool culture may be positive but cannot differentiate carriage from acute infection. During the first week of illness, blood cultures are positive in about 90% of patients, but culture positivity decreases in the next 2 weeks to less than 50% during the third week of illness. Stool cultures are usually negative during the first week but are generally positive by the third week. Bone marrow cultures give the highest yield, with up to 95% being positive; they should be considered in suspected cases with negative blood culture results. Bone marrow cultures may be positive even after several days of antimicrobial treatment, when blood cultures have become negative. Urine cultures and cultures of punch biopsies of rose spots may also be positive. The string test to obtain samples of bile from the duodenum has likewise yielded positive cultures. The peripheral leukocyte count is usually normal, but leukopenia, which occurs in about 20% of cases, may be suggestive of enteric fever. Fecal leukocytes are generally present.

PCR testing lacks sensitivity for diagnosis from blood and other specimens. Serologic tests that detect serum antibodies against *Salmonella* Typhi have poor sensitivities and specificities,[13] and they rarely provide useful information to guide management of the patient.

The differential diagnosis of enteric fever is broad and depends in part on the area of the world where the infection was acquired.[14] All causes of sustained fever are in the differential diagnosis, including infective endocarditis (Chapter 61), disseminated tuberculosis (Chapter 299), brucellosis (Chapter 286), tularemia (Chapter 287), *Mycoplasma pneumoniae* infection (Chapter 293), rickettsial infections (Chapter 302) including Q fever, and viral infections such as infectious mononucleosis (Chapter 348). Depending on the site of acquisition, diseases such as malaria (Chapter 316), amebic abscesses of the liver (Chapters 137 and 323), and visceral leishmaniasis (Chapter 319) also enter into the differential diagnosis.

TREATMENT

The emergence of widespread antimicrobial resistance has complicated the treatment of all *Salmonella* infections.[15,16] Any general guidance must be subject to local resistance profiles and the results of susceptibility testing.

Enterocolitis

The primary approach to the treatment of *Salmonella* enterocolitis is fluid and electrolyte replacement. Drugs with antiperistaltic effects, such as loperamide (4 mg orally initially followed by 2 mg after each unformed stool up to 16 mg per day), can relieve cramps and reduce diarrhea, but they should not be used in patients who are febrile or have bloody diarrhea because they can prolong the course of the disease (Chapter 262).

Salmonella enterocolitis is usually self-limited, and antimicrobial therapy has little effect on mild disease. Antimicrobial therapy typically is reserved for patients who are febrile, have bloody diarrhea, or are at high risk for invasive disease. In the presence of gross bloody diarrhea, however, antimicrobial therapy should be withheld until the possibility of infection with Shiga toxin–producing *E. coli* has been eliminated because antimicrobial therapy may increase the frequency of hemolytic-uremic syndrome 17-fold.

When antimicrobial therapy is reasonable, ciprofloxacin (500 mg every 12 hours orally or 400 mg every 12 hours intravenously for 3 to 5 days or until defervescence) is usually effective. An extended-spectrum cephalosporin such as ceftriaxone (2 g intravenously every 12 to 24 hours for 3 to 7 days) is an alternative. Other agents, such as amoxicillin and trimethoprim-sulfamethoxazole, have also been widely used in severely ill adults, but many strains of *Salmonella* are now resistant to these agents. Azithromycin (1000 mg orally once on the first day, followed by 500 mg once daily to complete a 7-day course) may be an alternative.

Enteric Fever

Fluoroquinolones (e.g., ciprofloxacin 500 mg orally twice a day for 7 to 14 days or 400 mg intravenously until oral therapy can be started) are the agents of choice to treat enteric fever in many parts of the world. Where resistance is sufficiently common, an alternative is ceftriaxone (2 g every 12 to 24 hours for adults and 75mg/kg/day for children, given intravenously or intramuscularly for 7 to 14 days), which can cure 95% of patients.[A1,A2] In treated patients, the temperature usually returns to normal after 3 to 5 days of therapy, but it may take longer in patients treated with extended-spectrum cephalosporins than in patients treated with fluoroquinolones.

Azithromycin (500 mg/day orally for 7 days) is effective in the treatment of patients with uncomplicated typhoid fever[A3] caused by multidrug-resistant and some extensively drug-resistant strains. The oral route of administration makes it a particularly attractive choice in settings where multidrug resistance is common and intravenous extended-spectrum cephalosporins are impractical, unavailable, or too expensive. Severe disease due to extensively drug-resistant *Salmonella* Typhi may respond to meropenem (1 g intravenously every 8 hours for 7 to 14 days).

Among the salmonellae causing enteric fever, resistance to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole has emerged worldwide. Outbreaks of extensively drug-resistant, including ceftriaxone-resistant, *Salmonella* Typhi are occurring in South Asia. If the *Salmonella* isolate is shown to be susceptible by antimicrobial susceptibility testing, however, ampicillin (25 mg/kg intravenously every 6 hours), chloramphenicol (50 mg/kg/day orally or intravenously, divided into four doses), or trimethoprim-sulfamethoxazole (4/20 mg/kg intravenously or orally every 12 hours) may be given for 7 to 14 days.

Patients often require supportive care with intravenous saline, correction of electrolyte and acid-base disturbances, and, in the setting of intestinal bleeding, blood transfusion. If perforation is suspected, abdominal imaging should be performed to evaluate for free air. If perforation seems likely, laparotomy should be performed as soon as possible to repair it. In the setting of perforation, antimicrobial therapy should be broadened to cover bowel flora.

Steroid therapy is beneficial in some patients with severe enteric fever complicated by coma, delirium, or shock. Dexamethasone is administered at doses of 3 mg/kg initially, followed by 1 mg/kg every 6 hours for 48 hours. Steroids can mask the signs and symptoms of abdominal perforation and should not be continued for more than 48 hours. Salicylates should be avoided.

Bacteremia

The agents of choice to treat *Salmonella* bacteremia are the fluoroquinolones, such as ciprofloxacin (400 mg every 12 hours intravenously), and the extended-spectrum cephalosporins,[A4] such as ceftriaxone (2 g every 12 to 24 hours intravenously). When the salmonellae are known to be susceptible, ampicillin (1 to 2 g intravenously every 4 to 6 hours) or trimethoprim-sulfamethoxazole (8 mg/kg/day of the trimethoprim component intravenously) can be used. Chloramphenicol (50 mg/kg/day orally or intravenously, divided into four doses) is another option. Antimicrobial susceptibility testing is necessary because of the emergence of infections resistant to the fluoroquinolones, extended-spectrum cephalosporins, and sometimes both.

In cases of sustained bacteremia, the possibility of endovascular infection or osteomyelitis should be investigated. For transient bacteremia or bacteremia without localization, therapy is continued for 7 to 14 days. With localization to bone, aneurysms, heart valves, and various other sites, antimicrobial therapy should be given for much longer periods (e.g., 6 weeks and even longer for osteomyelitis). Surgical drainage, removal of foreign bodies, or resection of an aneurysm is often necessary to cure localized infection. The possibility of schistosomiasis (Chapter 326) should be considered and treated, when present, in patients with sustained *Salmonella* bacteremia. Patients with HIV infection (Chapter 358) tend to experience repeated relapses after treatment courses for *Salmonella* bacteremia. In these patients, initial treatment with ciprofloxacin for 2 weeks or longer is recommended.

Carriers

Chronic carriers (i.e., >1 year) of salmonellae other than *Salmonella* Typhi are uncommon. Stools of convalescent carriers spontaneously become negative during a period of weeks to months, and no therapy should be given.

For patients with persistent carriage despite adequate antimicrobial therapy and without an identifiable anatomic abnormality, chronic suppressive therapy may be considered.[17] The rare chronic carrier of typhoidal *Salmonella* serovars other than Typhi (usually infected with *Salmonella* Paratyphi A, B, or C) may also be treated. Treatment of carriers is with a ciprofloxacin (500 to 750 mg orally twice daily); amoxicillin (6 g/day orally in three or four divided doses plus probenecid 2 g/day in divided doses); or trimethoprim-sulfamethoxazole (160/800 mg twice daily) plus rifampicin (300 mg twice daily).

Patients who experience relapse usually have gallbladder disease (most often calculi) and will not be cured with antimicrobial therapy alone. Cholecystectomy plus antimicrobial therapy may cure these patients, but it is doubtful that the carrier state alone is a sufficient indication for cholecystectomy. Patients with persistent urinary carriage and *S. haematobium* infection (Chapter 326) should be treated with praziquantel before eradication of *Salmonella* Typhi is attempted.

Chronic carriers who do not prepare food and who practice adequate personal hygiene usually do not constitute a public health hazard. Therefore, after the institution of appropriate personal hygienic precautions, and in the absence of evidence of a chronic carrier infecting others, cholecystectomy is probably not indicated to eradicate the carrier state.

PREVENTION

The widespread presence of salmonellae in the animal kingdom means that reducing the risk for *Salmonella* infections requires a multifaceted approach.[18] *Salmonella* infection is best prevented by protecting the water supply, preventing fecal contamination during food production, cooking and refrigerating foods, pasteurizing milk and milk products, and handwashing before preparing foods. Travelers should judiciously avoid consuming untreated water (including ice), raw vegetables, and fruits. Food should be cooked or peeled, and drinks should be boiled, carbonated, or commercially bottled.

No licensed vaccine is available for *Salmonella* infection other than for *Salmonella* Typhi. Travelers should be vaccinated before going to areas that are endemic for typhoid fever. Two types of effective vaccines[A5] are available in the United States. One is the typhoid Vi capsular polysaccharide vaccine, which is administered as a single intramuscular injection, with booster doses given every 2 years if needed. This vaccine provides a degree of herd protection against typhoid fever when it is used at the population level. The other licensed typhoid fever vaccine type is the oral live attenuated Ty21a vaccine. Revaccination is necessary every 5 years, if indicated. Ty21a vaccine should not be used in immunocompromised persons or those receiving antimicrobials. Both types of vaccines confer greater than 75% protective efficacy. A third type of vaccine, the Vi polysaccharide protein-conjugate vaccines, are recommended as a single dose from age 6 months in typhoid-endemic countries,[A6,A7] but these vaccines are not yet licensed in the United States.

Vaccines afford only partial immunity to typhoid fever. Persons who have been vaccinated should still restrict their diets to avoid potentially contaminated food and fluids. When cases of imported typhoid are identified in the United States, the local health department should be informed and will monitor stool cultures. Typhoid fever acquired in the United States is typically investigated by the public health department to identify potential sources and chronic carriers.

PROGNOSIS

Mortality in patients with *Salmonella* enterocolitis is rare. Outbreaks in nurseries and among the elderly in nursing homes are associated with the highest case-fatality ratios (>5%), with death occurring as a result of dehydration and electrolyte imbalance. Mortality from nontyphoidal *Salmonella* bacteremia is not uncommon, can be as high as 15% in sub-Saharan Africa,[19] and is most likely to occur in the very young, the very old, the malnourished, and the immunocompromised.

Before the advent of antimicrobial therapy, the case-fatality ratio of typhoid fever was 15 to 20%, but it is now less than 1% in industrialized countries.

However, the case-fatality ratio for typhoid fever in Africa remains over 5% in patients who do not require surgery[20] and is far higher among those who do.

In the era before antimicrobial therapy, 5 to 10% of patients who recovered from typhoid fever had relapses. Relapses continued to occur in 10 to 15% of patients treated with chloramphenicol, ampicillin and trimethoprim-sulfamethoxazole, but relapse seemed to be much less frequent (<5%) among those treated with ceftriaxone and fluoroquinolones. Relapses of typhoid fever may be treated with the same antimicrobial regimen as for the initial attack or with an alternative regimen, depending on the results of antimicrobial susceptibility testing. Long-term suppressive therapy has been suggested for patients who experience frequent relapses.[21]

Intestinal perforation is the leading cause of death from enteric fever. Intestinal bleeding or perforation occurs in about 5% of patients. In patients who require surgery for gastrointestinal perforation, the 30-day mortality rate is 9%.

Up to 3% of patients recovering from *Salmonella* Typhi and nontyphoidal *Salmonella* infection become chronic carriers, persistently shedding the organism in their stool. Most persistently infected patients are immunocompetent, and about two thirds have relapsing diarrhea, indicating that they are not truly asymptomatic.

285 SHIGELLOSIS

CALMAN A. MACLENNAN

DEFINITION

Shigellosis results from inflammation of the large intestine due to infection with bacteria of the genus *Shigella*. Clinical presentation is either with acute watery diarrhea or bloody diarrhea, known as dysentery, and is commonly accompanied by fever.[1] Shigellosis is a major global health problem compounded by increasing levels of antimicrobial resistance. It is the most common cause of diarrheal deaths for which no vaccine is currently available.

The Pathogen

Bacteria of the genus *Shigella,* family Enterobacteriaceae, are facultative anaerobic, nonmotile gram-negative bacilli. The four species are distinguished by the O-antigen component of lipopolysaccharide. *Shigella flexneri,* which has 15 serotypes, is the most common cause of shigellosis in low- and middle-income countries. *Shigella sonnei,* which is responsible for the majority of shigellosis in high-income countries, exists as just one serotype. *Shigella dysenteriae* occurs as 15 serotypes, including serotype 1, which has been responsible for outbreaks of shigellosis. *Shigella boydii,* which consists of 19 serotypes and is relatively uncommon, is found mostly in South Asia.

EPIDEMIOLOGY

Shigella is a human-restricted pathogen. Transmission most commonly occurs via the fecal-oral route, predominantly from direct person-to-person contact or via fomites. Infection is more common among populations in which overcrowding is common and without access to clean water and proper sanitation. A low number of bacilli, as little as 10 organisms for *S. dysenteriae* and 180 for *S. flexneri* and *S. sonnei,* is required for infection.

Transmission also occurs through contaminated food and water. *Shigella* was the third most common pathogen associated with food-borne gastroenteritis in the United States in 2016. Transmission by infected asymptomatic food-handlers presents a particular risk. In settings in which open defecation is common, transmission can be facilitated through house flies. Shigellosis is also increasingly recognized as a sexually transmitted disease, particularly among men who have sex with men.[2]

Shigellosis is predominantly a disease of low- and middle-income countries. Worldwide, *Shigella* is the second most common cause of diarrheal death, following rotavirus (which is also the most common cause of moderate to severe diarrhea; Chapter 350), and it is the most common bacterial cause. *Shigella* is the main pathogen associated with dysentery (attributable fraction 64%), and the second most attributable pathogen for watery diarrhea (attributable fraction 13%). The Global Burden of Disease 2019 report estimated about 150,000 worldwide deaths attributable to *Shigella*, with about 95,000 occurring among children under 5 years of age. Disability-adjusted life years lost to shigellosis are much higher and are estimated at about 10.5 million overall, about 8.5 million of which are lost in children under age 5 years.[3] By serotyping, 66% of *Shigella* isolates are *S. flexneri,* predominantly *S. flexneri* 2a, whereas 24% are *S. sonnei,* 5% are *S. dysenteriae,* and 5% are *S. boydii*.

Children under 5 years and adults who live in poor and crowded circumstances are at high risk of shigellosis.[4] Daycare centers present an environment where transmission of shigellosis is common. At the other end of the age spectrum, the elderly are also at increased risk of shigellosis, especially elderly individuals living in residential care facilities.

The incidence of shigellosis is much lower in high-income countries compared with low- to middle-income countries. Nevertheless, shigellosis is the second most common cause of acute gastroenteritis outbreaks in the United States after norovirus (Chapter 350). Shigellosis is common in the military, and *Shigella* has been estimated to be responsible for 2 to 9% of cases of travelers' diarrhea (Chapter 265).

S. dysenteriae type 1 was responsible for four pandemics with high attack rates and case fatality rates between 1968 and the 1990s. For unknown reasons, *S. dysenteriae* type 1 has largely disappeared in the 21st century, but has the potential to reemerge, particularly in settings of natural disasters with displaced peoples and poor sanitation and hygiene.

Although incidence levels have remained high, deaths due to shigellosis have decreased, likely because of improved management with antibiotics, oral rehydration solution, supplementation of zinc and vitamin A, and less preinfection baseline malnutrition. The change in profile of *Shigella* species, with the disappearance of *S. dysenteriae* type 1 and increased proportion of mild shigellosis due to *S. sonnei* in developed countries, also may be responsible.

PATHOBIOLOGY

Low-dose inocula of *Shigella* are able to resist gastric acid and transit to the intestine, where watery diarrhea is induced by the action of several factors, including *Shigella* enterotoxins 1 and 2 (ShET 1 and 2). More severe disease is induced by the secretion of Shiga toxin by *S. dysenteriae* type 1. The primary site of *Shigella* infection and multiplication is the colon, where *Shigella* bacteria outcompete commensal bacteria of the microbiota and then penetrate the mucus lining of the intestine by the secreting of mucinases that allow them to access the intestinal epithelium.

Shigella lacks fimbriae for adhesion to the colonic epithelium and instead gains entry through invasion of M cells overlying Peyer patches and subsequent phagocytosis by macrophages. The bacteria escape from the phagolysosome into the cytoplasm, where they trigger pyroptotic death of the macrophage, thereby resulting in their release into the lamina propria. Pyroptosis triggers the innate immune system to produce an inflammatory response, with production of proinflammatory cytokines, including interleukin (IL)-1, IL-8, IL-18, and interferon (IFN)-γ. The inflammatory response results in the recruitment of neutrophils to the site of infection and disruption of epithelial tight junctions,

However, the case-fatality ratio for typhoid fever in Africa remains over 5% in patients who do not require surgery[20] and is far higher among those who do.

In the era before antimicrobial therapy, 5 to 10% of patients who recovered from typhoid fever had relapses. Relapses continued to occur in 10 to 15% of patients treated with chloramphenicol, ampicillin and trimethoprim-sulfamethoxazole, but relapse seemed to be much less frequent (<5%) among those treated with ceftriaxone and fluoroquinolones. Relapses of typhoid fever may be treated with the same antimicrobial regimen as for the initial attack or with an alternative regimen, depending on the results of antimicrobial susceptibility testing. Long-term suppressive therapy has been suggested for patients who experience frequent relapses.[21]

Intestinal perforation is the leading cause of death from enteric fever. Intestinal bleeding or perforation occurs in about 5% of patients. In patients who require surgery for gastrointestinal perforation, the 30-day mortality rate is 9%.

Up to 3% of patients recovering from *Salmonella* Typhi and nontyphoidal *Salmonella* infection become chronic carriers, persistently shedding the organism in their stool. Most persistently infected patients are immunocompetent, and about two thirds have relapsing diarrhea, indicating that they are not truly asymptomatic.

285 SHIGELLOSIS

CALMAN A. MACLENNAN

DEFINITION

Shigellosis results from inflammation of the large intestine due to infection with bacteria of the genus *Shigella*. Clinical presentation is either with acute watery diarrhea or bloody diarrhea, known as dysentery, and is commonly accompanied by fever.[1] Shigellosis is a major global health problem compounded by increasing levels of antimicrobial resistance. It is the most common cause of diarrheal deaths for which no vaccine is currently available.

The Pathogen

Bacteria of the genus *Shigella,* family Enterobacteriaceae, are facultative anaerobic, nonmotile gram-negative bacilli. The four species are distinguished by the O-antigen component of lipopolysaccharide. *Shigella flexneri,* which has 15 serotypes, is the most common cause of shigellosis in low- and middle-income countries. *Shigella sonnei,* which is responsible for the majority of shigellosis in high-income countries, exists as just one serotype. *Shigella dysenteriae* occurs as 15 serotypes, including serotype 1, which has been responsible for outbreaks of shigellosis. *Shigella boydii,* which consists of 19 serotypes and is relatively uncommon, is found mostly in South Asia.

EPIDEMIOLOGY

Shigella is a human-restricted pathogen. Transmission most commonly occurs via the fecal-oral route, predominantly from direct person-to-person contact or via fomites. Infection is more common among populations in which overcrowding is common and without access to clean water and proper sanitation. A low number of bacilli, as little as 10 organisms for *S. dysenteriae* and 180 for *S. flexneri* and *S. sonnei,* is required for infection.

Transmission also occurs through contaminated food and water. *Shigella* was the third most common pathogen associated with food-borne gastroenteritis in the United States in 2016. Transmission by infected asymptomatic food-handlers presents a particular risk. In settings in which open defecation is common, transmission can be facilitated through house flies. Shigellosis is also increasingly recognized as a sexually transmitted disease, particularly among men who have sex with men.[2]

Shigellosis is predominantly a disease of low- and middle-income countries. Worldwide, *Shigella* is the second most common cause of diarrheal death, following rotavirus (which is also the most common cause of moderate to severe diarrhea; Chapter 350), and it is the most common bacterial cause. *Shigella* is the main pathogen associated with dysentery (attributable fraction 64%), and the second most attributable pathogen for watery diarrhea (attributable fraction 13%). The Global Burden of Disease 2019 report estimated about 150,000 worldwide deaths attributable to *Shigella*, with about 95,000 occurring among children under 5 years of age. Disability-adjusted life years lost to shigellosis are much higher and are estimated at about 10.5 million overall, about 8.5 million of which are lost in children under age 5 years.[3] By serotyping, 66% of *Shigella* isolates are *S. flexneri,* predominantly *S. flexneri* 2a, whereas 24% are *S. sonnei,* 5% are *S. dysenteriae,* and 5% are *S. boydii*.

Children under 5 years and adults who live in poor and crowded circumstances are at high risk of shigellosis.[4] Daycare centers present an environment where transmission of shigellosis is common. At the other end of the age spectrum, the elderly are also at increased risk of shigellosis, especially elderly individuals living in residential care facilities.

The incidence of shigellosis is much lower in high-income countries compared with low- to middle-income countries. Nevertheless, shigellosis is the second most common cause of acute gastroenteritis outbreaks in the United States after norovirus (Chapter 350). Shigellosis is common in the military, and *Shigella* has been estimated to be responsible for 2 to 9% of cases of travelers' diarrhea (Chapter 265).

S. dysenteriae type 1 was responsible for four pandemics with high attack rates and case fatality rates between 1968 and the 1990s. For unknown reasons, *S. dysenteriae* type 1 has largely disappeared in the 21st century, but has the potential to reemerge, particularly in settings of natural disasters with displaced peoples and poor sanitation and hygiene.

Although incidence levels have remained high, deaths due to shigellosis have decreased, likely because of improved management with antibiotics, oral rehydration solution, supplementation of zinc and vitamin A, and less preinfection baseline malnutrition. The change in profile of *Shigella* species, with the disappearance of *S. dysenteriae* type 1 and increased proportion of mild shigellosis due to *S. sonnei* in developed countries, also may be responsible.

PATHOBIOLOGY

Low-dose inocula of *Shigella* are able to resist gastric acid and transit to the intestine, where watery diarrhea is induced by the action of several factors, including *Shigella* enterotoxins 1 and 2 (ShET 1 and 2). More severe disease is induced by the secretion of Shiga toxin by *S. dysenteriae* type 1. The primary site of *Shigella* infection and multiplication is the colon, where *Shigella* bacteria outcompete commensal bacteria of the microbiota and then penetrate the mucus lining of the intestine by the secreting of mucinases that allow them to access the intestinal epithelium.

Shigella lacks fimbriae for adhesion to the colonic epithelium and instead gains entry through invasion of M cells overlying Peyer patches and subsequent phagocytosis by macrophages. The bacteria escape from the phagolysosome into the cytoplasm, where they trigger pyroptotic death of the macrophage, thereby resulting in their release into the lamina propria. Pyroptosis triggers the innate immune system to produce an inflammatory response, with production of proinflammatory cytokines, including interleukin (IL)-1, IL-8, IL-18, and interferon (IFN)-γ. The inflammatory response results in the recruitment of neutrophils to the site of infection and disruption of epithelial tight junctions,

ABSTRACT

Shigellosis results from inflammation of the large intestine due to infection with bacteria of the genus *Shigella*. Clinical presentation is either with acute watery diarrhea or bloody diarrhea, known as dysentery, and is commonly accompanied by fever. Shigellosis is a major global health problem compounded by increasing levels of antimicrobial resistance. It is the most common bacterial cause of diarrheal deaths, and no vaccine is currently available.

TABLE 285-1 CLINICAL SYNDROMES AND COMPLICATIONS OF SHIGELLOSIS

STAGE	TIME OF APPEARANCE AFTER ONSET OF ILLNESS	SYMPTOMS AND SIGNS	PATHOLOGY AND PATHOGENESIS
Prodrome	Earliest findings	Fever, chills, myalgias, anorexia	None or early colitis with cytokine response
Watery diarrhea	0-3 days	Fever, abdominal cramps, loose stools	Mild colitis with fecal leukocytes and erythrocytes
Bloody diarrhea	1-3 days	Frequent stools containing blood and mucus, abdominal cramps and tenderness, fever, anorexia	Colitis with fecal leukocytes and erythrocytes
Dysentery	1-5 days	Frequent small-volume stools consisting of blood, mucus, and pus; severe abdominal cramps; tenesmus	More extensive colitis with crypt abscesses and mucosal ulcerations
Acute complications	3-7 days	Seizures, obtundation, bacteremia, colonic obstruction, mucosal perforation, peritonitis	Severe colitis, terminal ileitis
Additional acute complications due primarily to infection with *Shigella dysenteriae* type 1	3-7 days	Toxic megacolon, leukemoid reaction, hemolytic-uremic syndrome	Severe colitis, expression of Shiga toxin
Postinfectious syndromes	1-3 weeks	Reactive arthritis, with or without urethritis and conjunctivitis	Autoimmune inflammatory response, most common in individuals expressing HLA-B27 antigen

HLA = human leukocyte antigen.

thereby allowing *Shigella* bacteria to have direct access to the lamina propria. The ensuing tissue damage results in mucosal abscesses and erosions, as well as the characteristic release of blood and mucus into the intestinal lumen and stool.

With access to the basolateral surface of intestinal epithelial cells, shigellae induce their own uptake through the assembly of the type III secretion system (T3SS) needle apparatus encoded on the virulence plasmid and injection of virulence effectors into epithelial cells. In contrast to macrophage pyroptosis, this process promotes the survival of epithelial cells and suppresses the production of antimicrobial peptides. Injected proteins cause rearrangement of the actin cytoskeleton and fragmentation of the epithelial cell Golgi apparatus. This effect permits phagocytosis of *Shigella* bacteria, followed by release into the cytoplasm, replication, and infection of neighboring epithelial cells by clathrin-dependent endocytosis. As shigellae invade throughout the epithelium, acquired immunity is suppressed by the action of *Shigella* effector proteins, which downregulate inflammation and disrupt B-cell and T-cell activities. Over the course of about 5 to 7 days, the *Shigella* infection is normally cleared by the influx of neutrophils.

CLINICAL MANIFESTATIONS

Asymptomatic infection is common. The onset of symptoms typically follows an incubation period of up to 4 days, but the incubation period can be twice as long when infection is with *S. dysenteriae* type 1.

Symptoms at the outset are commonly fever, chills, myalgias, and anorexia, with watery diarrhea ensuing a few hours later (Table 285-1). Although the classic presentation of shigellosis is dysentery, most symptomatic cases of shigellosis present as watery diarrhea and are difficult to distinguish from other causes of diarrhea (Chapter 126). In more severe cases, shigellosis progresses to bloody diarrhea/dysentery.

Disease is most severe with *S. dysenteriae* type 1 and with *S. flexneri,* which has a high incidence in low- to middle-income countries, and less severe with *S. sonnei,* which is common in high-income countries. *S. boydii* is mostly associated with mild disease. In otherwise healthy individuals, symptoms often resolve within a few days.

Frank dysentery may be manifested as multiple episodes (as high as 40/day) of small-volume bloody stools that are often mixed with mucus. Diarrhea is often accompanied by lower abdominal cramps and tenesmus. Intestinal complications include rectal prolapse, toxic megacolon secondary to intestinal inflammation, and obstruction. Rarely, patients may develop intestinal perforation and peritonitis.

Extraintestinal complications include seizures in 5 to 30% of children admitted to the hospital with shigellosis. Occasional patients may develop obtundation or encephalopathy. Bacteremia is a rare complication, mostly seen in individuals infected with HIV or young and malnourished children. Meningitis, osteomyelitis, and arthritis are uncommon. Shigellosis in pregnancy may result in preterm labor and transmission to the neonate. Shigellosis with *S. dysenteriae* type 1 can result in the hematologic complications of leukemoid reactions (Chapter 153) and hemolytic uremic syndrome (Chapter 158).

In high-income countries, up to 1 to 2% of individuals with shigellosis, particularly patients with the human leukocyte antigen (HLA)-B27 gene, will develop reactive arthritis (Chapter 244), which is an immune-mediated seronegative spondyloarthropathy. The arthritis can be accompanied by other extra-intestinal manifestations including uveitis, urethritis, and erythema nodosum. *Shigella* infection also increases the risk of subsequent irritable bowel syndrome (Chapter 123).

DIAGNOSIS

No clinical manifestation can reliably distinguish shigellosis from other causes of watery diarrhea. Stool microscopy, which typically shows red blood cells and leukocytes is also nonspecific. Modern diagnosis relies on quantitative polymerase chain reaction (PCR) testing of stool[5] (Chapter 262), which is more sensitive than stool culture,[6] followed by culture, either from stool directly or from a rectal swab, to determine antibiotic susceptibility.[7] Work is underway to develop low-cost molecular technologies suitable for field use in low- to middle-income countries.

TREATMENT

In many individuals, particularly in high-income countries where shigellosis presents as uncomplicated diarrhea, the disease is self-limiting and no treatment is required or recommended for uncomplicated diarrhea. When diarrhea results in dehydration, supportive treatment with oral rehydration solution is often needed[8]; intravenous fluids (glucose and saline) can be reserved for severe dehydration or the inability to tolerate oral fluids. Oral rehydration solution should be supplemented with zinc sulfate (20 mg), which reduces the duration of shigellosis. Antimotility agents should not be used because of concern about prolonged symptoms and shedding as consequences of lengthened exposure to *Shigella* bacteria in the intestinal tract.

Antibiotics reduce the duration of fever, diarrhea, and bacterial shedding when given to treat *Shigella* dysentery. Antibiotics are routinely recommended for dysentery, for severe illness in immunocompromised patients, and during epidemics, but antibiotics are not routinely recommended for non-febrile watery diarrhea.

A range of antibiotics appear to be equally effective, but rising antimicrobial resistance increasingly limits treatment options, which initially should be based on local susceptibility data, when available, and then on sensitivity profile of the individual patient's infections when such results are available. For adults, empirical oral ciprofloxacin (500 mg orally once daily for 3 days) is recommended (Fig. 285-1). Where local strains of *Shigella* are ciprofloxacin-resistant, other options include oral azithromycin (500 mg orally twice daily for 1 day), cefixime (400 mg once daily for 3 days), or trimethoprim-sulfamethoxazole (160 mg/800 mg twice daily for 5 days). Intravenous or intramuscular ceftriaxone (1 g daily for 3 days for adults and 50 to 75 mg/kg daily for 2 to 5 days for children) is the antibiotic of choice for severe shigellosis and when vomiting or unconsciousness precludes

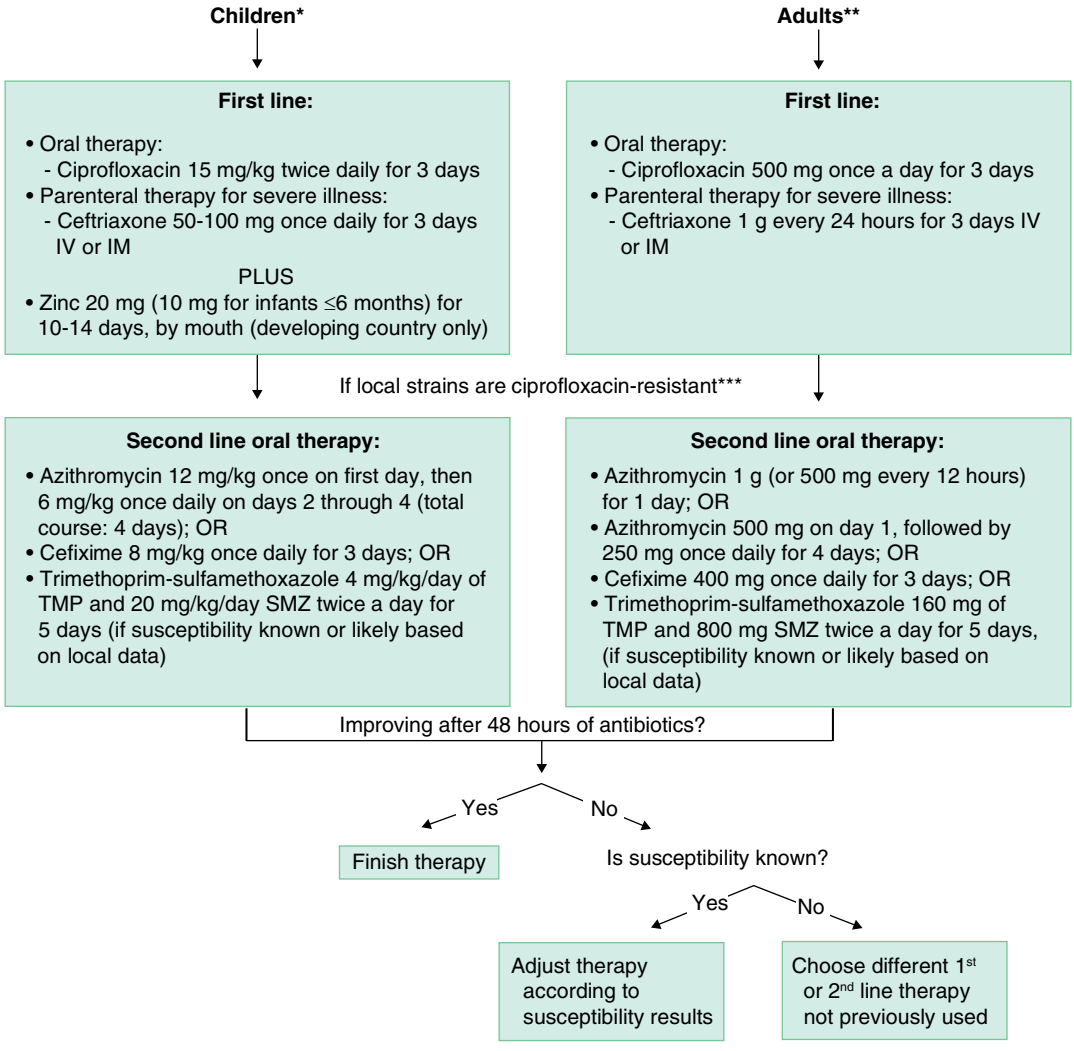

FIGURE 285-1. Treatment of shigellosis.

the use of oral medication. Immunosuppressed patients should be treated for 7 to 10 days.

Once sensitivity data are available by molecular methods[9] or culture, the antibiotic regimen should be adjusted. Antimicrobial resistance to shigellosis is a major global public health concern.[10] Ciprofloxacin-resistant *S. sonnei* emerged in South Asia and have spread widely.[11,12] If the *Shigella* isolate has a minimal inhibitory concentration of 0.12 µg/mL or greater for ciprofloxacin, fluoroquinolones must not be used due to concern about increasing the severity of the disease and prolonging bacterial shedding.[13] Azithromycin-resistant *Shigella* is common among men who have sex with men and people living with HIV.[14] Resistance to third-generation cephalosporins has been reported in Asia.

In patients who have severe intestinal complications such as obstruction, perforation, and peritonitis, surgery may be indicated. Rectal prolapse is usually correctable by manipulation, and the rectal mucosa must be kept moist until reduction is performed as soon as possible.

PREVENTION

Personal hygiene is important for preventing the spread of shigellosis, particularly in the context of outbreaks. Handwashing with soap and water greatly reduces the quantity of *Shigella* bacteria carried on the hands. Adequate sanitation and access to clean water are key for breaking the cycle of infection given the fecal-oral route of *Shigella* transmission.

The development of an effective vaccine is a priority, especially given the growing problem of antibiotic resistance. Currently, 4-valent O-antigen–based vaccines are in clinical trials,[15,16] but no internationally recognized vaccine is licensed for shigellosis.

PROGNOSIS

Although shigellosis is often self-limiting with no sequelae in high-income countries, it is associated with excess mortality and stunted growth in the year following infection among children in lower-middle-income countries.[17] *S. dysenteriae* type 1 has most often been associated with extra-intestinal complications, such as hemolytic-uremic syndrome (Chapter 158) that can result in long-term renal impairment or failure. Reactive arthritis (Chapter 244) and irritable bowel syndrome (Chapter 123) secondary to shigellosis usually resolve in about 12 months and do not become chronic.

286 BRUCELLOSIS

EDSEL MAURICE T. SALVANA

DEFINITION

Brucellosis, previously known as Malta fever, Mediterranean fever, or undulant fever, is a zoonotic disease caused by bacteria of the genus *Brucella*. Human infection, which has protean manifestations, is acquired via direct contact, ingestion, or inhalation. Most disease is acquired by eating unpasteurized dairy products or undercooked meat. Occupational infection typically occurs by inhalation, inadvertent exposure to live attenuated vaccines, or through contamination of exposed wounds and mucous membranes. Human-to-human transmission occurs but is rare. Brucellosis remains a significant public health and economic burden in many countries despite advances in detection, treatment, and prevention. In regions where the disease is endemic, brucellosis has far-reaching deleterious effects on humans and animals alike.[1]

The Pathogen

Brucella is a slow-growing, small, aerobic, nonmotile, non-encapsulated, non–spore-forming, gram-negative coccobacillus. *Brucella abortus* (from cattle, bison, elk), *B. suis* (from pigs and feral swine), *B. melitensis* (from sheep, goats, and camels), and *B. canis* (from dogs) are the species that most commonly infect humans. Genetic analysis shows a high degree of homology among different species despite disparate preferred hosts. Virulence factors can also vary between and within species. Whole-genome sequencing shows that *Brucella* is closely related to saprophytic soil-dwelling bacteria, and some species within *Ochrobactrum* are genetically very similar to *Brucella*.[2]

EPIDEMIOLOGY

More than 500,000 cases of brucellosis are reported yearly to the World Health Organization (WHO) from 100 countries, but the true incidence is estimated to be 10 to 25 times higher. *B. melitensis* infection accounts for most diagnosed cases owing to difficulties in immunizing free-range sheep and goats, which harbor this species. Most cases occur in the Mediterranean region,[3] Latin America, the Arabian Gulf, China, and the Indian subcontinent. *B. abortus* infection occurs worldwide and is responsible for most outbreaks in Mexico, China, Greece, and Brazil. *B. suis* is found in the United States, South America, and Southeast Asia. *B. canis* infection occurs in North America, South America, Japan, and Central Europe. In Africa, high rates of *Brucella* seropositivity have been reported in local wildlife[4] and in communities that keep livestock and consume unpasteurized milk.

In animals, brucellosis is a chronic infection that can persist throughout life. Control programs in animals have decreased human brucellosis dramatically in the United States from more than 6000 cases in 1947 to about 80 to 120 cases annually, with most cases reported in Texas, California, Arizona, and Florida.[5]

Brucella infection in the United States occurs mostly through direct contact with animals or animal secretions in high-risk groups, including slaughterhouse workers, farmers, dairy workers, and veterinarians. Laboratory workers handling infected animals or *Brucella* cultures are also at risk. More than one half of reported cases are associated with meat processing, particularly from "kill areas." Many cases of *B. abortus* infection in veterinarians are from accidental exposure to live vaccines used to immunize livestock. Human infections in hunters of feral swine occur sporadically. Imported goat milk and cheese from Mexico (unpasteurized) is an important source of *B. melitensis* infection. Brucellosis contracted abroad may not become symptomatic until the traveler returns. Childhood brucellosis, which occurs mostly in school-aged children, accounts for 3 to 10% of all reported cases worldwide.

Human-to-human transmission is rare and has occurred through sexual transmission, breastfeeding, blood transfusion, bone marrow transplantation, nosocomial exposure, and perinatally. For example, a family cluster of brucellosis in China involved vertical transmission and sexual transmission following occupational exposure of the index case.[6]

PATHOBIOLOGY

Pathogenesis

Entry of *Brucella* organisms into humans is usually through the mucosal route, via ingestion or inhalation. The bacteria then translocate through the intestinal mucosa or the respiratory epithelium. Oral, conjunctival, and direct skin inoculation can also occur. *Brucella* in naïve individuals induces a delayed inflammatory response, with mostly macrophages and dendritic cells involved in the early response. Granulomas composed of lymphocytes, infected macrophages, and dendritic cells eventually form. Phagocytosed *Brucella* subsequently spread to regional lymph nodes. If host defenses within the lymph nodes are overwhelmed or the burden of infection is high, bacteremia follows. The usual incubation period from infection to bacteremia is 2 to 4 weeks. Bacteremia is accompanied by phagocytosis of free *Brucella* organisms by macrophages, primarily in the spleen, liver, and bone marrow, where small, noncaseating granulomas form and can serve as persistent sources of infection.[7]

Brucella organisms avoid initial detection by the host through multiple mechanisms. Its cell wall lipopolysaccharide differs significantly from most other bacteria in two important ways: *Brucella* has very little effect on toll-like receptor type 4 (TLR4) activation, and it is resistant to complement activation. In addition, *Brucella* deploys a protein that interferes with TLR signaling. Upon successful entry into the host, about 10% of *Brucella* organisms in phagosomes are able to survive acidification and lysosome fusion to form an endosomal *Brucella*-containing vacuole, thereby maintaining a persistent presence.[8] To replicate, *Brucella* organisms intercept traffic between the endoplasmic reticulum and the Golgi apparatus.

Apart from structurally helping to maintain cell envelope integrity, *Brucella* outer membrane proteins Omp25/Omp31 contribute to virulence by mediating direct interactions between the brucellae and mammalian cells.[9] Other important virulence factors that enable pathogenic *Brucella* to survive the hostile intracellular niche include catalase, superoxide dismutase, alkyl hydroperoxide reductase, cytochrome oxidase, nitric oxide reductase, *Brucella* virulence factor A, and the *Nramp1* gene.

Inflammation from the innate host immune response is likely the main driver of pathology because no secreted proteolytic enzymes or bacterial toxins have been found. *Brucella* induces the production of host proinflammatory cytokines and metalloproteinases, which cause tissue damage, particularly in osteoarticular areas of the body.

Immunity

Innate immunity to *Brucella* is mediated by activation of toll-like receptors, which produce inflammatory cytokines and recruit phagocytic cells, such as macrophages and dendritic cells, which attempt to control the initial infection and activate adaptive immunity. Platelets also release cytokines, which recruit more monocytes and macrophages in an attempt to clear infection.

Similar to other intracellular organisms, cell-mediated immunity is the predominant adaptive immunologic response to *Brucella*. Macrophages, activated with T helper 1 (T_H1)–type cytokines (most importantly interferon-γ, tumor necrosis factor-α, interleukin-1, and interleukin-12), kill *Brucella*. Antibody production seems to play a peripheral role in clearing infection and is not considered essential. Increasing evidence suggests that *Brucella*-infected neutrophils dampen adaptive immunity and may act as "Trojan horses" that aid dispersal of bacterial infection throughout the body.[10]

CLINICAL MANIFESTATIONS

Strain-Specific Illness

Brucella abortus is usually associated with mild to moderate sporadic disease. *B. suis* and *B. melitensis* infections are associated with suppurative or disabling complications and can have a prolonged course. Infection with *B. canis* has an insidious onset, relapses frequently, and has a chronic but relatively mild course. Two marine species, *B. pinnipedialis* (from seals) and *B. ceti* (from porpoises and dolphins) can cause neurobrucellosis in humans. *Brucella microti* (from the common vole and red fox) has a high potential for pathogenicity, but no instances of human infection have been reported. Three strains of *B. inopinata* (*BO1*, breast implant infection; *BO2*, chronic destructive pneumonia; *BO3*, generalized lymphadenopathy and pneumonia) are genetically similar to atypical *Brucella* from frogs. *Brucella* spp. are considered select agents for bioterrorism (Chapter 19) owing to their pathogenicity and long-term viability.[11]

Clinical Syndromes

Clinically, human brucellosis infection can be divided into subclinical illness, acute or subacute disease, and localized disease. After treatment, some patients develop relapsing infection or chronic disease (Table 286-1).

Subclinical Illness

Asymptomatic or clinically unrecognized human brucellosis often occurs in high-risk groups, including slaughterhouse workers, farmers, and veterinarians. The diagnosis is usually made through serologic means. More than 50%

ABSTRACT

Brucellosis, previously known as Malta fever, Mediterranean fever, or undulant fever, is a zoonotic disease caused by intracellular bacteria of the genus *Brucella*. Human infection, which has protean manifestations, is acquired via direct contact, ingestion, or inhalation. Most disease is acquired by eating unpasteurized dairy products or undercooked meat. Occupational infection typically occurs by inhalation, inadvertent exposure to live attenuated vaccines, or through contamination of exposed wounds and mucous membranes. Human-to-human transmission occurs but is rare. Brucellosis remains a significant public health and economic burden in many countries and is proving a resilient disease despite advances in detection, treatment, and prevention. *Brucella* is a potential agent of bioterrorism due to its pathogenicity.

TABLE 286-1 CLINICAL CLASSIFICATION OF HUMAN BRUCELLOSIS

CLASSIFICATION	DURATION OF SYMPTOMS BEFORE DIAGNOSIS	MAJOR SYMPTOMS AND SIGNS	DIAGNOSIS	COMMENTS
Subclinical		Asymptomatic	Positive (low-titer) serology, negative cultures	Occurs in abattoir workers, farmers, and veterinarians
Acute and subacute	Up to 2-3 months and 3 months to 1 year, respectively	Malaise, chills, sweats, fatigue, headache, anorexia, arthralgias, fever, splenomegaly, lymphadenopathy, hepatomegaly	Positive serology, positive blood or bone marrow cultures	Presentation can be mild, self-limited (*B. abortus*) or fulminant with severe complications (*B. melitensis*)
Localized	Occurs with acute or chronic untreated disease	Related to involved organs	Positive serology, positive cultures in specific tissues	Bone or joint, genitourinary, hepatosplenic involvement most common
Relapsing	2-3 months after initial episode	Same as acute illness but may have higher fever and more fatigue, weakness, chills, and sweats	Positive serology, positive cultures	May be extremely difficult to distinguish relapse from reinfection
Chronic	>1 year	Nonspecific presentation, but neuropsychiatric symptoms and low-grade fever most common	Low titer or negative serology, negative cultures	Most controversial classification; localized disease may be present

of abattoir workers and up to 33% of veterinarians have high anti-*Brucella* antibody titers but no history of recognized clinical infection. Children in endemic areas frequently have subclinical illness.

Acute and Subacute Disease

After an incubation period of several weeks or months, acute brucellosis may occur as a mild, transient illness (*B. abortus* or *B. canis*) or as an explosive, toxic illness with the potential for multiple complications (*B. melitensis* or *B. suis*). Approximately 50% of patients have an abrupt onset over days, but the remainder have an insidious onset over weeks and may present with fever of unknown origin (Chapter 259).[12] Symptoms in brucellosis are protean and nonspecific. More than 90% of patients experience malaise, chills, sweats, fatigue, and weakness. More than 50% of patients have myalgias, anorexia, and weight loss. Some patients complain of arthralgias, cough, testicular pain, dysuria, ocular pain, or blurring of vision.

Few localizing physical signs are apparent. Fever, with temperatures often greater than 39.4° C (103° F), occurs in 95% of patients. An undulating or intermittent fever pattern is not unusual. A pulse-temperature deficit (i.e., relative bradycardia) may occur. Splenomegaly is present in 10 to 15% of cases, and lymphadenopathy occurs in about 14% of patients. Axillary, cervical, and supraclavicular lymphadenopathy are most frequent and may be related to hand wounds or oropharyngeal routes of infection. Hepatomegaly is less frequent. Laboratory findings in acute or subacute disease may include mild anemia; lymphopenia; or neutropenia (especially with bacteremia); lymphocytosis; thrombocytopenia; or, in rare cases, pancytopenia.

Localized Disease and Complications

Brucella organisms may occur at multiple sites or can localize to almost any organ. Infection usually targets the bones, joints, central nervous system, heart, lung, spleen, testis, liver, gallbladder, kidney, prostate, pancreas, thyroid, and skin. Among osteoarticular complications, sacroiliitis is the most common acute presentation and should prompt evaluation for brucellosis in the appropriate setting. Spondylitis and spondylodiscitis, particularly in the lumbar area, are also common and can be associated with paravertebral, epidural, and psoas abscesses. Peripheral arthritis, prosthetic joint infections, osteomyelitis, tenosynovitis, and bursitis are less frequent but should prompt an evaluation in endemic areas. Brucellosis in pregnancy has been associated with spontaneous abortions, congenital abnormalities, and neonatal infections.

DIAGNOSIS

Many common illnesses mimic brucellosis, and a thorough history is essential, including occupation, travel to endemic areas, avocations, and ingestion of at-risk food and beverages. Nucleic acid amplification tests can rapidly and highly accurately diagnose brucellosis in blood, bodily fluids, or tissue samples.[13] Since nucleic acid can persist in tissues, however, nucleic acid amplification tests cannot be used to confirm cure. Such testing is especially useful when no viable material is available for culture.

Despite the accuracy of nucleic acid amplification testing, the most conclusive means of establishing the diagnosis of brucellosis is the recovery of the organism from a culture from normally sterile body fluid or tissue. Sensitivity of cultures ranges from 15 to 90%, depending on the methods used, species, timing, stage of disease, prior use of antimicrobial agents, and the specimen type. Handling of *Brucella* cultures is potentially hazardous to laboratory personnel, so the laboratory should be informed if this organism is suspected. Longer incubation times may increase yield.

Blood cultures are positive in 10 to 30% of cases of acute brucellosis, but this rate can be as high as 85% with *B. melitensis*. The sensitivity of blood cultures decreases with increasing duration of illness. In *B. melitensis* infection, bone marrow cultures are more sensitive than blood cultures. In localized brucellosis (e.g., lymph nodes, spleen, liver, skeletal system), cultures of purulent material or tissues usually yield *Brucella* organisms. Culture of cerebrospinal fluid is positive in 45% of patients with meningitis.

Immunologic Testing

In the absence of microbiologic confirmation or specimens for nucleic acid amplification testing, a presumptive diagnosis can be made by history and serology.[14] The most frequently used test, which is the standard (tube) agglutination test (SAT), measures antibody titers against *B. abortus* antigen. A four-fold or greater rise in titer over 2 weeks is considered significant. A presumptive case is one in which the agglutination titer is positive (1:160 in endemic areas; 1:80 in nonendemic areas) in single or serial specimens, with symptoms consistent with brucellosis. This test detects antibodies to *B. abortus, B. suis,* and *B. melitensis* but not to *B. canis*. Serologic confirmation of *B. canis* infection requires *B. canis* or *B. ovis* antigen. Titers are not useful in differentiating relapsing infection from other febrile illnesses in patients with a history of past *Brucella* infections.

In chronic brucellosis, antibodies which do not agglutinate at neutral pH increase and replace agglutinating antibodies, and so a complementary test that detects antibodies to smooth lipopolysaccharide, such as the *Brucella* Coombs test is recommended. The U.S. Centers for Disease Control and Prevention uses a modified SAT known as the *Brucella* microagglutination test (BMAT). False-positive SAT titers have been associated with *Brucella* skin testing, cholera vaccination, or infection with *Vibrio cholerae, Francisella tularensis*, or *Yersinia enterocolitica*.

TREATMENT

Effective treatment of *Brucella* infection requires antibiotics that can penetrate the intracellular compartment, have little or no toxicity even with the prolonged use needed to prevent relapse, and are bactericidal for adequate treatment of central nervous system infection and endocarditis (Table 286-2). There remains considerable debate over which antibiotic regimen is best. In adults, the combination of oral doxycycline at 100 mg orally twice a day for 6 weeks plus either streptomycin 1 g intramuscularly daily for 3 weeks or gentamicin 3 to 5 mg/kg/day for 1 to 2 weeks is the preferred regimen.[A1] A quinolone plus rifampicin may be better tolerated than doxycycline plus rifampicin as alternative therapy.[15] These regimens are less effective for cases of spondylitis, which may require up to 3 months of treatment with any of the previous regimens. For *Brucella* endocarditis (Chapter 61), medical treatment alone is associated with a much higher risk of death compared with a combined medical and surgical approach. About 25% of prosthetic joint infections respond to medical therapy, but the remainder need débridement or revision.[16]

TABLE 286-2 TREATMENT FOR BRUCELLOSIS

	TREATMENT	COMMENTS
Acute, with no endocarditis or CNS involvement; not pregnant; children older than 8 years old	Preferred: oral doxycycline (200 mg/day) for 6 weeks PLUS IM streptomycin (1 g/day) for 2-3 weeks OR IM gentamicin 3-5 mg/kg/day for 1-2 weeks Alternatives: oral ofloxacin (800 mg/day) PLUS rifampin (15 mg/kg/day) for 6 weeks; oral doxycycline (200 mg/day) PLUS rifampin (15-20 mg/kg/day, maximum 900 mg) for 6 weeks; oral doxycycline (200 mg/day) PLUS TMP-SMX (10/50 mg/kg, maximum 320/1600 mg in 2 doses) for 6 weeks; oral TMP-SMX (10/50 mg/kg, maximum 320/1600 mg in 2 doses) PLUS rifampin (15-20 mg/kg/day, maximum 900 mg) for 6 weeks (preferred regimen in children <8 years old); oral rifampin or doxycycline at above doses × 6 weeks PLUS gentamicin (5 mg/kg IM in 1-3 doses) for 5-10 days	Treatment of choice by WHO; widely used; low rate of relapse; IM administration of streptomycin may be difficult; gentamicin is more readily available
In children <8 years old and pregnant women	Oral TMP-SMX (10/50 mg/kg, maximum 320/1600 mg in 2 doses) PLUS rifampin (15-20 mg/kg/day, maximum 900 mg) for 6 weeks	
CNS disease	Oral doxycycline (200 mg/day) PLUS rifampin (15-20 mg/kg/day, maximum 900 mg) and TMP-SMX (10/50 mg/kg, maximum 320/1600 mg in 2 doses) for 6 weeks, but can extend longer if with residual disease	Third-generation cephalosporin such as ceftriaxone 2 g IV q12 × 6 weeks can be substituted for one of the agents if susceptible
Localized disease	Surgically drain abscesses PLUS antimicrobial therapy for ≥6 weeks	
Brucella endocarditis	Bactericidal drugs (fluoroquinolones, aminoglycosides, β-lactams if susceptible; for 6 weeks; see earlier for dosing); early valve replacement may be necessary	Possible aortic valve destruction and/or major arterial emboli

CNS = central nervous system; IM = intramuscular; IV = intravenous; TMP-SMX = trimethoprim-sulfamethoxazole; WHO = World Health Organization.

PREVENTION

The control of human brucellosis is directly related to prevention programs in domestic animals and the avoidance of unpasteurized milk and milk products. In slaughterhouses, important means of prevention include careful wound dressing, the use of protective glasses and clothing, the prohibition of raw meat ingestion, and the use of previously infected (immune) individuals in high-risk areas. Work is ongoing to find an effective vaccine for humans. Postexposure antimicrobial prophylaxis is controversial.

PROGNOSIS

The majority of infected individuals recover completely without sequelae if diagnosed early with prompt initiation of therapy. With early antimicrobial therapy, brucellosis is usually cured, and cases of relapsing brucellosis, chronic brucellosis, or localized complications are rare. With acute brucellosis, however, severe weakness and fatigue may frequently make patients unable to work for up to 2 months.

Immunity to reinfection follows initial *Brucella* infection in the majority of individuals. Of the patients who die of brucellosis, 84% have endocarditis involving a previously abnormal aortic valve, often associated with severe heart failure.

Relapsed Infection

Up to 10% of patients with brucellosis relapse after antimicrobial therapy because of intrinsic or acquired resistance to antibiotics. Antimicrobial agents may be unable to penetrate efficiently enough to kill all intracellular bacteria. Relapses usually occur 3 to 6 months after completion of therapy but may be seen up to 2 years after initial treatment. Relapsing infection is difficult to distinguish from reinfection in high-risk groups with continued exposure. Relapses are associated with inappropriate or insufficient antimicrobial therapy, growth on blood cultures during the initial presentation, and an acute onset of disease. Triple-combination doxycycline (200 mg a day in 1 to 2 doses for 6 weeks), streptomycin (1 g IV/IM once a day for 2 to 3 weeks), and rifampicin (600 to 900 mg once a day for 6 weeks) clears *Brucella* DNA better than dual therapy and may be useful for treatment in chronic brucellosis.

Chronic brucellosis, which is defined as disease that persists for more than 1 year, occurs in perhaps 5 to 20% of cases. A majority of patients classified as having chronic brucellosis really have persistent disease caused by inadequate treatment of the initial episode, or they have focal disease in bone, liver, or spleen. About 20% of patients diagnosed with chronic brucellosis complain of persistent fatigue, malaise, and depression. Treatment is as for the acute infection, typically using alternative antibiotics other than what were used acutely.

287 TULAREMIA AND OTHER *FRANCISELLA* INFECTIONS

KAREN C. BLOCH AND FRED A. LOPEZ

DEFINITION

Tularemia is an infectious zoonosis caused by *Francisella tularensis*, which is an aerobic, pleomorphic, gram-negative bacillus. Many animal species harbor this organism, most prominently rabbits, squirrels, and muskrats. Humans acquire the infection by various means, including direct contact with infected animal tissues, ingestion of contaminated water or meat, the bite of an infected tick or deer fly, or inhalation of aerosolized bacteria.[1] *F. tularensis* is highly infectious and is a well-recognized risk to laboratory personnel who manipulate culture plates of the organism. Deer flies can transmit the infection from animals to humans, and colloquially the disease is often referred to as *rabbit fever* or *deer fly fever*.

The Pathogen

The organism occurs in two major subspecies (biovars).[2] *F. tularensis* biovar *tularensis* (type A), which is the common North American biovar, can be further divided into two subtypes. A.1, which is the most virulent strain, is endemic to the central eastern regions along the west coast of the United States. Subtype

The Pathogen

The organism occurs in two major subspecies (biovars).[2] *F. tularensis* biovar *tularensis* (type A), which is the common North American biovar, can be further divided into two subtypes. A.1, which is the most virulent strain, is endemic to the central eastern regions along the west coast of the United States. Subtype

ABSTRACT

Tularemia is a zoonotic infection that causes human disease throughout the world. Infection is spread by direct contact with animals, ingestion of contaminated food or water, an insect bite, or inhalation of aerosolized bacteria. This latter mechanism of transmission makes tularemia a potential agent of bioterrorism. Classically, six distinct clinical syndromes have been described but with significant overlap among these presentations. Symptoms typically develop within a week of exposure, and fever is almost universally present. Clinical presentations include ulceroglandular disease characterized by skin lesions and lymphadenopathy, typhoidal disease presenting as an undifferentiated febrile illness, oculoglandular disease characterized by ocular inflammation and regional lymphadenopathy, oropharyngeal disease characterized by pharyngitis, and pneumonic disease. Regardless of the syndrome, the recommended treatment is streptomycin or gentamicin, but other agents, including doxycycline and fluoroquinolones, have activity against this organism. No vaccine is commercially available, and prevention entails reducing exposure to vectors.

A.II, which causes a milder disease, is localized to the Western United States.[3] In contrast, *F. tularensis* biovar *holarctica* (type B) is less virulent and occurs commonly in Europe and Asia.[4] Type B is most frequently isolated from rodent species, including muskrats, mice, beavers, voles, water voles, and prairie dogs. An additional subspecies, *F tularensis* biovar *mediasiatica*, has been identified in Central Asia but does not cause human disease.

EPIDEMIOLOGY

Tularemia has been reported in the United States, Canada, Mexico, Japan, and Europe.[5] In Iran, seroprevalence ranges from 2 to 14%, with the highest rates in farmers.[6] It has not been reported in the United Kingdom or the Southern Hemisphere. In the United States, reported cases declined from a high of 2291 cases in 1939 to fewer than 300 cases per year now (E-Fig. 287-1). In the United States, the highest annual incidence rates are in Arkansas (3.1 per 100,000), South Dakota (1.9 per 100,000), and Nebraska (0.9 per 100,000).[7]

In the United States, tularemia is usually acquired from tick bites or from contact with infected animals, especially rabbits. Tick-associated cases, which now constitute the most common route of transmission, primarily occur during the summer. The most common vectors in the United States are the wood tick (*Dermacentor andersoni*), the dog tick (*Dermacentor variabilis*), and the Lone Star tick (*Amblyomma americanum*). A smaller peak of autumn and winter cases is a consequence of rabbit hunters skinning and eviscerating their game. Public health education materials aimed at decreasing the hazards of handling wild animals have contributed to the reduction of tularemia in hunters. Mosquitoes are common vectors in Northern Europe.[8] Occasionally infections occur following the bite of an infected animal or, more likely, from the bite of an animal whose mouth was contaminated from recently eating a diseased animal. The latter likely explains most instances of cat-bite tularemia. Contaminated fresh water is another source of infection.[9]

Males experience a higher incidence of disease than females in all age groups, probably owing to greater exposure to the outdoors and animal-related activities. Persons in all age groups are affected, with children 5 to 14 years of age and older adults most prominently infected. In the United States, Native American and Alaska Natives experience the highest annual incidence (0.5 per 100,000); Whites have a lower risk (0.04 per 100,000), but Blacks and Asians/Pacific Islanders have the lowest risks (≤0.01 per 100,000).

Although tularemia is usually a sporadic infection, outbreaks of disease have been traced to laboratory exposure, contaminated groundwater, muskrat handling, dressing a dead hare, lawn mowing, and brush cutting. In the latter two cases, pneumonic tularemia occurred following creation of an environmental aerosol of organic material that had been contaminated with *F. tularensis* excreted in the urine and feces of infected rodents. An outbreak of oropharyngeal tularemia in Turkey affecting 55 patients was ultimately traced to contaminated tap water. Epidemiologic evaluation following diagnosis of oropharyngeal tularemia in six grape harvesters identified inadvertent crushing of an infected rodent in the freshly pressed grape must with subsequent ingestion as the route of transmission.[10] The organism can survive in water, mud, and straw for weeks to months. Human-to-human transmission has not been reported.

Tularemia's high infectivity (as few as 10 organisms induces pneumonic disease), its ease of dissemination, and the difficulty of rapidly diagnosing acute illness are characteristics that make tularemia a Tier 1 bioterrorism agent (Chapter 19). Infections must be reported immediately to local public health authorities to investigate both conventional and bioterrorist sources.

PATHOBIOLOGY

F. tularensis can infect humans through several portals of entry, including the skin, the mucous membranes, and the gastrointestinal and respiratory tracts. The organism persists intracellularly and can multiply within macrophages and other cells. After inoculation into the skin and subcutaneous tissue, local bacterial multiplication evokes a suppurative necrotic reaction, which is characterized by an initial polymorphonuclear response followed by an influx of macrophages and lymphocytes. These suppurative lesions evolve into granulomas. Bacteremia can occur both early and late during this process. The infection can disseminate to the lymph nodes, liver, spleen, lungs, and pleura. Viable *F. tularensis* can persist in tissues for long periods, thereby contributing to the tendency to relapse after treatment.

CLINICAL MANIFESTATIONS

Classically, the clinical manifestations of tularemia have been separated into six categories: ulceroglandular, glandular, oculoglandular, typhoidal, oropharyngeal, and pneumonic.[11] However, many patients have features of several types. The course of illness is determined by the portal of entry, the degree of systemic involvement, and the dose and virulence of the infecting strain of *F. tularensis*.

The general features of tularemia are similar regardless of the portal of entry. After exposure, the usual incubation period is 3 to 5 days (range, 1 to 21 days). The disease begins abruptly with the onset of fever (≥101° F), chills, malaise, and headache. Myalgia, vomiting, sore throat, and abdominal pain can also occur. Almost 50% of patients have a pulse rate that is substantially slower than would be anticipated based on the degree of fever (pulse-temperature dissociation). The fever may abate somewhat after 1 to 3 days, only to recur and continue, accompanied by other symptoms, for 2 to 3 weeks. Untreated, weight loss, easy fatigability, and lymphadenopathy may persist for weeks longer.

Ulceroglandular Disease

Ulceroglandular disease is the form of infection most readily recognized by physicians. In addition to fever and other constitutional symptoms, the patient calls attention to tender, swollen lymph nodes that drain an inoculation site. The nodes are usually axillary or inguinal, and a local lesion appears concurrently or 1 or 2 days before or after the lymphadenopathy. The lesions at the site of inoculation begin as small, red, tender, or painful papules that progress to pustules and then undergo necrosis to produce an ulcer with sharp, somewhat elevated edges and a flat base that becomes black (Fig. 287-1). Untreated, the ulcers heal over a period of weeks and leave scars.[12] Tick-induced infections produce lesions on the trunk, about the waist, and in the perineum, as well as local adenopathy. Children often have occipital and cervical adenopathy from tick bites on the neck and in the hair. Animal exposure often produces lesions, which may be multiple, on the hands and forearms. Because the organisms evoke a localized granulomatous response, frank lymphangitis does not occur in uncomplicated tularemia, but an occasional patient manifests a chain of nodules in sporotrichoid fashion along the lymphatic drainage.

Patients with such apparently localized disease often have symptoms and findings indicating a more widespread infection. Sore throat with or without an erythematous pharynx occurs. Chest radiography can show patchy infiltrates in the lower lobes, pleural effusions, and hilar adenopathy.

Glandular and Typhoidal Disease

Glandular disease is essentially the same clinical syndrome as ulceroglandular disease but without an obvious local lesion. The patient has fever, constitutional symptoms, and lymphadenopathy. The local lesion may have been on a part of the body where it was not seen, or it may have been small and already healed by the time the patient sought medical care. Glandular disease accounts for only 3 to 20% of cases.

In typhoidal disease, which accounted for nearly 50% of cases in a series of patients in Arkansas, the patient does not have lymphadenopathy and essentially presents with fever of unknown origin (Chapter 259). In these cases, the illness will not be diagnosed unless the physician specifically considers the possibility of tularemia.

Oculoglandular Disease

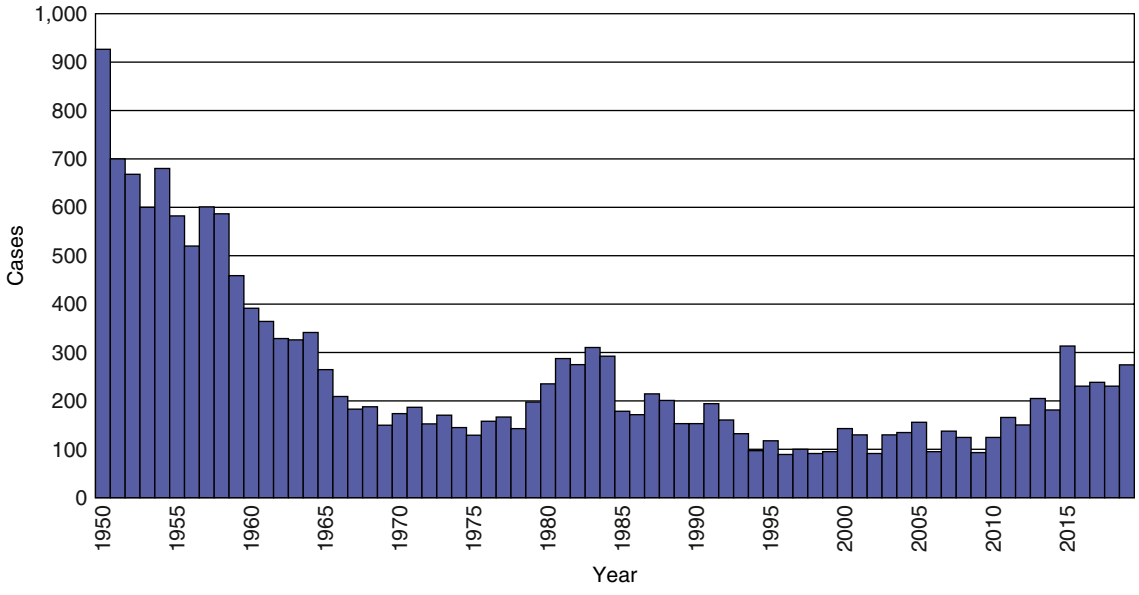
Oculoglandular disease is rare (<5% of cases) and occurs when the conjunctival sac is the portal of entry via an aerosol, splash, or contaminated fingers.[13] It is almost always unilateral and can have a dramatic presentation with inflamed, swollen eyelids, chemosis, and painful conjunctivitis. The palpebral conjunctiva often shows small yellow nodules and ulcers, counterparts to the skin lesions of ulceroglandular disease. The affected regional lymph nodes are those of the head and neck.

Oropharyngeal Disease

Oropharyngeal disease, which is also uncommon in the United States, occurs when the mucous membranes of the mouth and pharynx are the portal of entry. Contaminated water or food (inadequately cooked game meat) is the source. Painful exudative pharyngitis and tonsillitis, pharyngeal ulcers, and swollen retropharyngeal and cervical lymph nodes are seen.

Pneumonic Disease

Although pneumonia may be one aspect of the other tularemic syndromes, primary pneumonic tularemia, which is the form of the disease that would result from bioterrorism, accounts for about 10% of reported cases and occurs from inhalational exposure.[14] In addition to fever and malaise, patients may have a dry cough, substernal discomfort, pleural pain, dyspnea, and sore throat, but hemoptysis is uncommon. These pulmonary symptoms may not be very prominent in the context of the systemic illness. The physical examination reflects the extent and distribution of the pneumonic process, which may range



E-FIGURE 287-1. Tularemia cases reported annually in the United States, 1950-2019. (Source: https://www.cdc.gov/tularemia/statistics/index.html.)

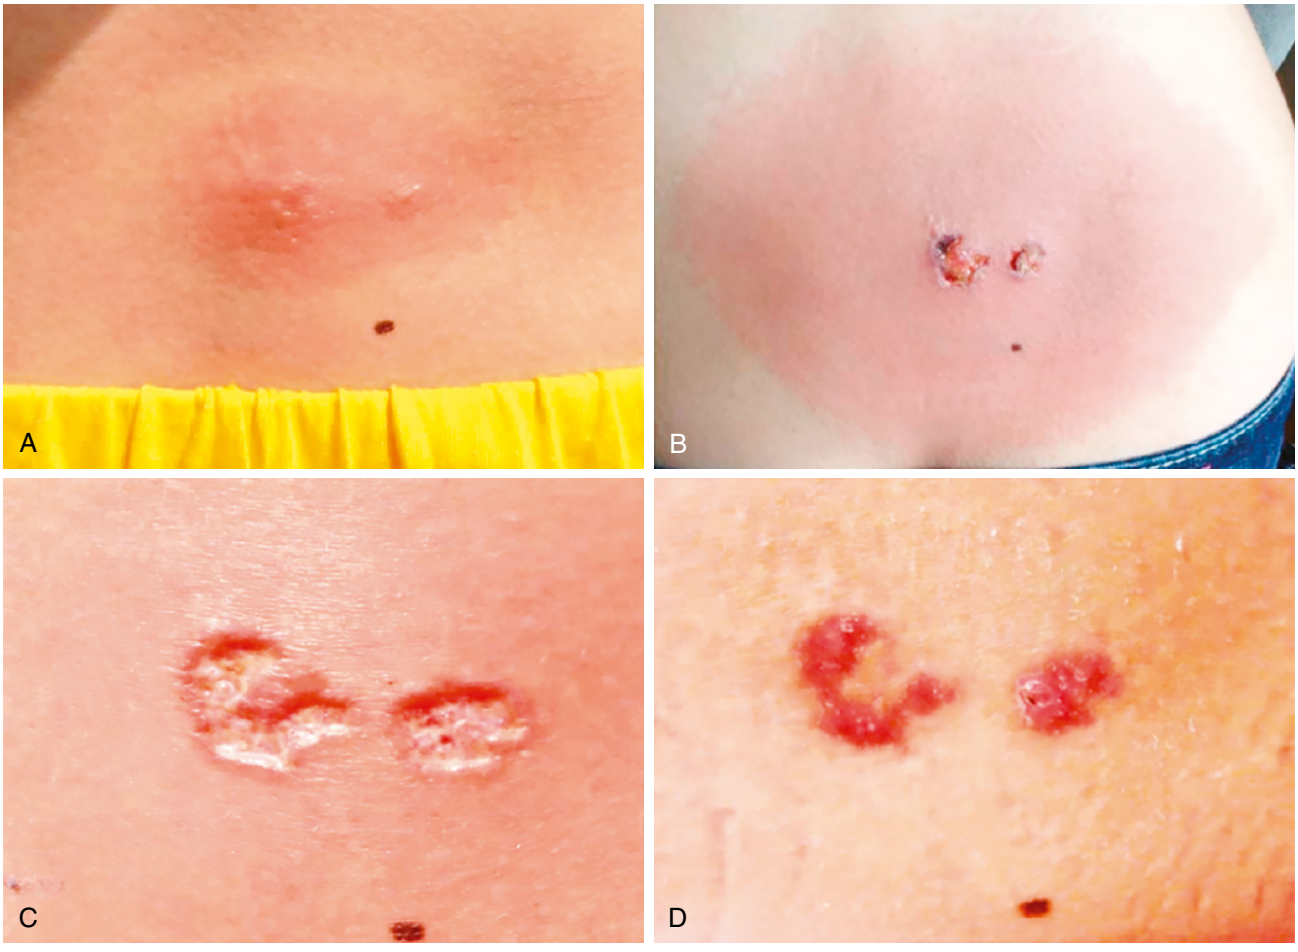


FIGURE 287-1. Ulcerative tularemia. (Source: Holland SD, Michelow IC. Tularemia masquerading as ecthyma. *J Pediatr*. 2016;178:299. doi:10.1016/j.jpeds.2016.07.023. [Epub 2016 Aug 22.])

from barely evident to frank consolidation with pleural effusion. Radiographic findings range from modest peribronchial infiltrates early in the illness to distinctive bronchopneumonia with effusion. Hilar adenopathy is present in more than one third of cases.

Other Clinical Presentations

Intestinal manifestations, including diarrhea, vomiting, or abdominal pain, may predominate. Cardiac involvement, including myocarditis and endocarditis, has been reported. Localized infections of prosthetic joints are increasingly recognized. Tularemia can also be associated with cranial neuropathies,[15] likely as an immune-mediated manifestation.

DIAGNOSIS

Routine laboratory studies are nonspecific. Leukocyte counts may be within normal limits or elevated; thrombocytopenia, elevated liver enzymes, and sterile pyuria occur with some frequency. For pneumonic disease, sputum examination is not helpful. Pleural effusions generally contain more than 1000 lymphocytes/μL. Gram stain results are typically negative, and pleural biopsies occasionally contain granuloma, thus inviting confusion with tuberculosis.

The suspected diagnosis of tularemia, initially based on exposure risk and clinical presentation, is confirmed by diagnostic testing. Identification of the organism in tissue specimens by polymerase chain reaction can provide rapid confirmation of the diagnosis.[16] Serum antibody levels do not reach diagnostic levels until after the 11th day of illness. A presumptive diagnosis can be made based on a single positive titer; a confirmed diagnosis requires seroconversion with a four-fold rise in antibody titers between acute and convalescent specimens.[17] Titers of both immunoglobulin M and immunoglobulin G antibodies may remain elevated for many years after the illness. False-positive serologic cross-reactions have been reported with *Brucella* (Chapter 286), *Legionella* (Chapter 290), *Salmonella* (Chapter 284), and *Yersinia* species (Chapter 288).

F. tularensis may be isolated from blood cultures and tissue specimens when media containing cysteine are used. Especially with typhoidal disease, the diagnosis can be made fortuitously when a positive blood culture is reported. Laboratory personnel should be notified when tularemia is suspected so that appropriate media can be used, incubation can be extended, and Biosafety Level 3 precautions are in place to protect against the production of hazardous aerosols.

Differential Diagnosis

The differential diagnosis of patients with tularemia is substantial. The local lesions can be confused with cat-scratch disease (Chapter 291), brown recluse spider bites (Chapter 98), *Mycobacterium marinum* infection (Chapter 300), herpes simplex infection (Chapter 345), and even syphilis (Chapter 295) and chancroid (Chapter 276) when the lesions are in the perineum or on the penis. Pneumonic tularemia resembles common community-acquired pneumonia (Chapter 85), as well as less common infections such as psittacosis (Chapter 294), legionellosis (Chapter 290), and Q fever (Chapter 302). The glandular and typhoidal forms can resemble typhoid fever (Chapter 284), brucellosis (Chapter 286), ehrlichiosis (Chapter 302), and other illnesses accompanied by nonspecific fevers.

TREATMENT

The preferred antimicrobials are streptomycin (1 g intramuscularly twice daily) or gentamicin (5 mg/kg intramuscularly or intravenously once daily), given for 10 to 14 days[18] (see https://www.cdc.gov/tularemia/clinicians/index.html). For patients with less severe illness, ciprofloxacin (500 to 750 mg orally twice daily for 10 to 14 days) is also effective; alternatively, doxycycline (100 mg orally twice daily for 14 to 21 days) can be used.

In patients who do not have a suggestive history of tick or animal exposure, tularemic pneumonia may be misdiagnosed as poorly responding community-acquired pneumonia (Chapter 85). Either levofloxacin (500 to 750 mg orally daily for a minimum of 5 days) or doxycycline (100 mg orally twice daily for a minimum of 5 days), as commonly used as empirical therapy for community-acquired pneumonia, has activity against tularemia; however, the duration of treatment must be 14 days for tularemia. Patients with glandular disease may require incision and drainage in addition to antibiotics for cure.

Treatment in pregnancy is complicated by the potential teratogenic effects of the first-line therapies. Limited data suggest that azithromycin may be an effective alternative for pregnant women, but the optimal dose and duration are not known and should be guided by expert consultation. Cranial neuropathy is usually treated with intravenous immunoglobulin therapy (0.4 g/kg/d for 5 days) rather than these antibiotics.

PREVENTION

Prevention of tularemia entails minimizing exposure to ticks and avoiding direct exposure to wild animals. Tick protection includes clothing that extends to the wrists and ankles, regular inspection for attached ticks, and the use of insect repellents containing diethyltoluamide (DEET). Gloves should be worn when skinning and dressing game animals, especially rabbits, and all wild rabbit and other game meats should be cooked thoroughly. A live, attenuated vaccine was used in the past to provide some protection to researchers working with *F. tularensis*, but it is no longer licensed in the United States or in Europe.

PROGNOSIS

Before treatment was available, acute tularemia often persisted for as long as 1 month, followed by several months of debility, with a mortality rate that approached 10%. When appropriately diagnosed and treated, however, the mortality rate from tularemia is now 1% or less, and most patients recover fully without long-term sequelae.[19]

PLAGUE AND OTHER *YERSINIA* INFECTIONS

PAUL S. MEAD AND CHRISTINA A. NELSON

The genus *Yersinia* currently contains 26 officially recognized species, of which three are known to be important human pathogens, *Yersinia pestis, Y. enterocolitica,* and *Y. pseudotuberculosis*. The remaining species are generally considered nonpathogenic and are most frequently isolated from environmental sources. Two possible exceptions are *Y. intermedia* and *Y. frederiksenii,* which have been isolated from clinical samples, thereby suggesting a possible role as rare human pathogens.

PLAGUE

DEFINITION

Plague is a life-threatening flea-borne disease that is best known as the cause of the Black Death of the Middle Ages.[1] The illness most often presents with regional lymphadenopathy but can also take the form of a primary pneumonia. Plague can be cured if treated promptly with appropriate antimicrobials.

The Pathogen

Plague is caused by *Y. pestis*, which is a microaerophilic, gram-negative, nonmotile, and nonsporulating coccobacillus that belongs to the family Enterobacteriaceae. *Y. pestis* can exist as a facultative intracellular pathogen and exhibits bipolar staining with Wayson, Giemsa, and Wright stains (Fig. 288-1). *Y. pestis* lacks a true capsule but has a carbohydrate-protein envelope comprising the *capsular* or *fraction 1 antigen*. Although only one serotype is thought to exist, most isolates can be classified into three principal biovars (*Antiqua, Mediaevalis*, and *Orientalis*) based on their ability to ferment glycerol and reduce nitrates. All three biovars occur in Asia, which is generally accepted as the continent where plague originated. Two biovars exist in Africa (*Antiqua* and *Orientalis*), but only *Orientalis* occurs naturally in the Americas. All are highly virulent and appear to cause virtually identical signs and symptoms in humans.

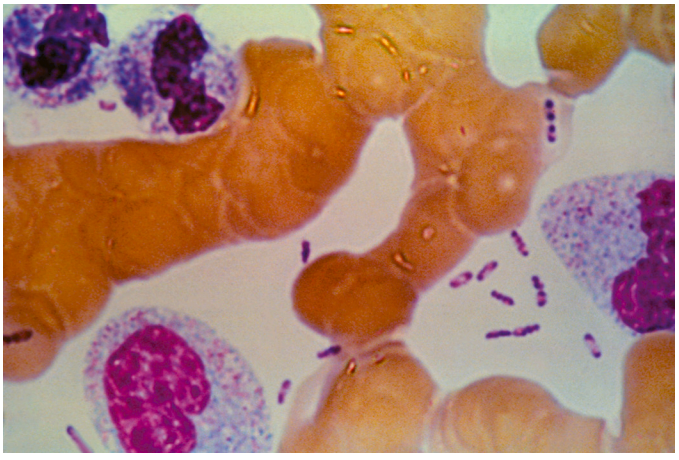

FIGURE 288-1. Wayson-stained blood smear showing bipolar staining bacilli with "safety pin" appearance from a fatal case of human plague. (Centers for Disease Control and Prevention.)

EPIDEMIOLOGY

Plague is endemic in discrete areas of Africa, Asia, and the Americas (E-Fig. 288-1), including the Western United States (Fig. 288-2).[2] In nature, *Y. pestis* is maintained by transmission cycles involving certain rodent species and their fleas, which act as vectors. Two general types of cycles have been postulated. Enzootic cycles involve low-level transmission among relatively resistant rodent species and are thought to pose little immediate risk to humans. Spread to more susceptible rodent species, however, can trigger an epizootic cycle in which the pathogen spreads rapidly through the rodent population, causing mass mortality. As rodent hosts die, infected fleas seek blood meals from nonrodent species, including humans. Although nonrodent mammals are typically dead-end hosts, some secondary transmission can occur, and rodent-consuming carnivores and raptors can potentially spread the disease to neighboring areas through the transport of infected rodent fleas. *Y. pestis* has some capacity to survive in soil, and recent work suggests a possible role for free-living ameba in maintaining *Y. pestis* in the environment.[3]

Humans can acquire plague through multiple routes, with the bite of an infected rodent flea being by far the most common (Fig. 288-3). Risk is greatest in endemic areas of the developing world where flea-infested commensal rats, especially *Rattus rattus* and *R. norvegicus*, live in close proximity to humans. The oriental rat flea, *Xenopsylla cheopis,* which is a particularly efficient vector of *Y. pestis*, feeds readily on both rats and humans. In the United States, contact with commensal rats is less common, and most cases result from the bites of fleas from other rodents, such as ground squirrels, prairie dogs, wood rats, and chipmunks. In this setting, flea bites are usually acquired during hiking, hunting, or other outdoor activities. Allowing dogs to sleep in their owners' beds also appears to increase risk, presumably from the fleas that dogs acquire while roaming outside.

Although less common, humans can also become infected with *Y. pestis* by close contact with other infected mammals. Percutaneous exposure by direct contact with infected tissues, such as while skinning a rabbit or rodent for meat, or by the bites or scratches of infected carnivores such as cats can transmit the organism. More concerning from a public health perspective is infection acquired by inhalation of infectious droplets. Inhalation of bacteria usually occurs by exposure to animals or humans who have pulmonary plague, and it results in primary pneumonic plague, a form of the disease that is often fatal and can spread from person to person under certain circumstances.

Despite the presence of plague-endemic areas on multiple continents, human infection is relatively uncommon. Prior to the discontinuation of routine notification in 2007, only 1000 to 6000 human plague cases were reported to the World Health Organization (WHO) each year. Over the last half century, the bulk of reported human cases has shifted from southeast Asia to sub-Saharan Africa. According to the most recently released WHO statistics covering the period 2013 through 2018, Madagascar, the Democratic Republic of Congo, Uganda, and Tanzania accounted for 97% of the world's reported cases (see E-Fig. 288-1). Another 3% were reported from three countries in

ABSTRACT

The genus *Yersinia* includes *Yersinia pestis*, which is the flea-transmitted cause of plague, as well as two enteric pathogens, *Y. enterocolitica* and *Y. pseudotuberculosis,* which are transmitted primarily through fecal-oral routes. The three species share a number of identified virulence factors, some of which are regulated in a temperature-dependent manner. Plague occurs in discrete, endemic areas in Asia, Africa, and North and South America. The enteric yersinioses are more cosmopolitan in distribution. Whereas human infection with *Y. pestis* is life-threatening without prompt antimicrobial treatment, the enteropathic *Yersinia* typically cause self-limited illness that does not require antimicrobial therapy.

the Americas—Bolivia, Peru, and the United States; Asian countries accounted for only 0.4% of total cases.

Much of the concern regarding plague stems not from the average case counts but from the potential for sudden outbreaks. In August 2017, for example, a man in Madagascar died of pneumonic plague during a long bush taxi ride that triggered an outbreak in which over 2400 suspected cases were identified.[4] Although it is likely that many of these patients did not actually have plague, the economic and social consequences were substantial.

In the United States, plague is found in the continental states west of the 100th meridian. New Mexico accounts for the majority of human cases, followed by Arizona, California, and Colorado (see Fig. 288-2). Since 2000, the annual number of cases has ranged from 1 to 17, with most cases occurring in the spring and summer. Cases are occasionally reported in other states, either due to travel to the west or to laboratory exposure, as occurred in Illinois in 2009. Occupation-related infection has occurred among veterinary staff, biologists, and trappers, including cases of primary pneumonic plague among persons handling cats or dogs with signs of plague pneumonia, pharyngitis, or oral abscesses. Although human-to-human spread of primary pneumonic plague has not been confirmed in the United States since 1924, possible person-to-person transmission was identified in 2014 during an outbreak in Colorado.

Concern has been raised that *Y. pestis* could be used as an agent of bioterrorism (Chapter 19). In most projected scenarios, bioterrorists would spread *Y. pestis* in an aerosol form, thereby potentially resulting in numerous primary pneumonic cases, a high mortality rate, and widespread panic. The possibility of engineered resistance to antimicrobials would need to be considered during an intentional release of *Y. pestis*.

PATHOBIOLOGY

Few bacteria are more pathogenic for humans than *Y. pestis*. The organism's virulence reflects the need to achieve high levels of bacteremia in order to ensure onward transmission to uninfected fleas. The process begins when *Y. pestis* enters the body, usually through the bite of an infected flea or other percutaneous exposure. Some bacteria are killed by polymorphonuclear leukocytes. Other bacteria, however, enter into mononuclear cells and are carried via lymphatics to the regional lymph nodes, where they replicate. Infected lymph nodes, termed buboes (Fig. 288-4), can appear edematous and congested early in the course of illness but exhibit little evidence of inflammatory infiltrates or vascular injury histologically. Within a few days, however, they contain massive numbers of *Y. pestis* and heavy neutrophil infiltrates, thereby causing the substantial swelling and tenderness that are the hallmark of bubonic plague. As the illness progresses, hemorrhagic necrosis and vascular damage in the node become apparent; some nodes spontaneously rupture. Additional complications, seen in autopsy specimens, include diffuse hemorrhagic splenic necrosis, renal glomeruli containing fibrin thrombi, and multifocal necrosis in the liver.

Of particular concern is hematogenous spread to the lungs, which can result in secondary pneumonic plague. Secondary pneumonic plague initially presents with scant sputum production and diffuse pulmonary infiltrates. Without prompt treatment, *Y. pestis* spreads from the interstitial spaces of the lung to the pulmonary alveoli; sputum increases in quantity and may become pink or blood tinged. At this point, a patient with secondary pneumonic plague can transmit infection to others through coughed respiratory droplets.

Inhalation of infectious droplets from humans or animals with pneumonic plague causes primary pneumonic infection, which is a rapidly progressive lung infection that is initially lobular, then lobar, and finally multilobar, with large numbers of *Y. pestis* present in the alveoli and pulmonary secretions (Fig. 288-5).

A small percentage of patients with plague develop septicemia in the absence of recognized buboes, pneumonia, or other signs of localized infection, a condition referred to as primary septicemic plague. These patients commonly have abdominal pain without other localizing symptoms, perhaps reflecting infection through the gastrointestinal tract or by a flea bite on the trunk in a location where regional lymph nodes are mostly internal and not clinically apparent.

Successful evasion of the host's immune system by *Y. pestis* is enabled by both chromosomal and plasmid-encoded virulence factors. The ability to escape from the host's innate immune defenses and disseminate to regional lymph nodes depends in part on a protease (Pla) encoded on the 9.5-kb plasmid that helps degrade fibrin clots and promote the production of excess plasmin, which can affect inflammatory exudates, break down extracellular proteins and basement membranes, and reduce levels of chemoattractants. Another virulence factor, *Yersinia* outer protein M, is one of many *Yersinia* outer proteins encoded by genes on the midsized (70 to 75 kb) plasmid of *Y. pestis*. Although such proteins are degraded by the Pla protease, *Yersinia* outer protein M is resistant to its activity and probably aids in the dissemination of *Y. pestis* by competing with platelets for thrombin, thereby reducing clotting, inhibiting

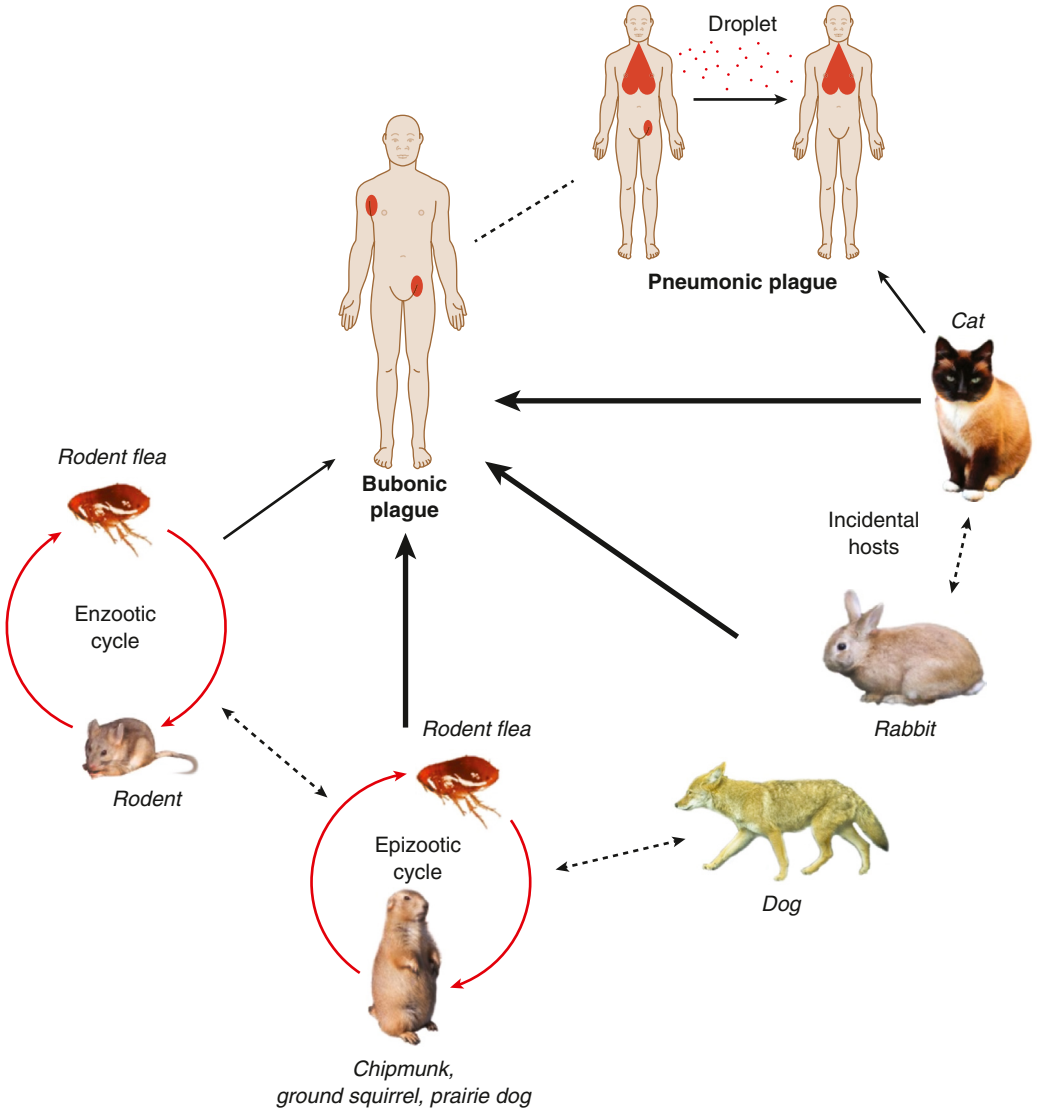

FIGURE 288-3. Ecology and transmission of plague. *Red circles* indicate zoonotic cycles. Common routes of transmission to humans indicated by *bold arrows* and uncommon routes by *thin arrows*. (Centers for Disease Control and Prevention.)

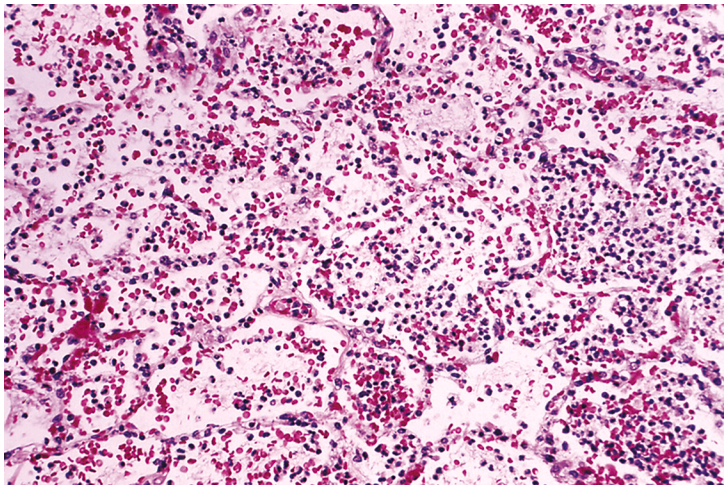

FIGURE 288-5. Photomicrograph of lung tissue from fatal case of primary pneumonic plague. Note filling of alveolar spaces with inflammatory cells and debris. (Centers for Disease Control and Prevention.)

the activation of platelets, and lowering local inflammatory responses.[5] Initial invasion and dispersal to regional lymph nodes also depends on the ability of *Y. pestis* to survive for at least brief periods inside host phagocytes. Survival in such environments is promoted by other *Yersinia* outer proteins that work in concert with a type III secretory apparatus to deliver into host phagocytes those *Yersinia* outer proteins that act as intracellular effectors. These effector proteins disturb the cytoskeletal dynamics of phagocytic cells and block their

FIGURE 288-6. Hand of a patient with plague displaying acral gangrene. (Centers for Disease Control and Prevention.)

production of proinflammatory cytokines. Affected phagocytes are rendered incapable of killing the invading *Y. pestis*, thereby allowing this bacterium to survive extracellularly in lymphoid tissues.

Survival of *Y. pestis* in mammalian hosts also depends on its ability to acquire sufficient quantities of iron for growth. The most important means of iron uptake in *Y. pestis* is a siderophore (yersiniabactin) system that can effectively compete with host iron-binding molecules for this essential nutrient. The capacity of *Y. pestis* to survive within host phagocytes is complemented during later stages of infection by the expression of a glycoprotein capsular antigen (caf1 or fraction 1 antigen) that confers resistance to phagocytosis. Expression of caf1 is temperature dependent, being repressed at the cooler temperatures found in the flea vector and upregulated at mammalian host body temperatures.

CLINICAL MANIFESTATIONS

The three most commonly observed forms of plague (in order of decreasing occurrence) are bubonic, septicemic, and pneumonic. Unusual manifestations of plague include meningitis, pharyngitis, skin ulcers, and osteomyelitis. In rare instances, *Y. pestis* has been inoculated through the conjunctiva, thereby resulting in oculoglandular plague. The incubation periods are 2 to 6 days for bubonic plague and 1 to 4 days for primary pneumonic plague.

Bubonic Plague

The characteristic swollen and tender lymph nodes (buboes) of bubonic plague usually appear in nodes located proximal to the site of initial inoculation (see Fig. 288-4). Most cases of bubonic plague in the United States are thought to be acquired from flea bites on the legs, as indicated by inguinal or femoral lymph node involvement on the side where the flea bite occurred. Axillary buboes, which are also common, result from the handling of an infected animal or carcass. Cervical buboes are uncommon in the United States but prevalent in some developing countries where people may sleep on the floor, thereby increasing their chance of being bitten about the head and neck by infectious fleas. Occasionally, a skin lesion or small papule appears at the site of an infectious flea bite or other source of inoculation.

As the architecture of the infected lymph nodes breaks down, large numbers of *Y. pestis* enter the circulation, thereby producing signs and symptoms typical of gram-negative sepsis, including fever, chills, myalgia, arthralgia, headache, malaise, and prostration. Disseminated intravascular coagulation (Chapter 161) can trigger thrombosis within capillaries, vascular necrosis, ecchymoses, acral gangrene, and cutaneous, mucosal, and serosal petechiae (Fig. 288-6).

Untreated patients with bubonic plague become increasingly toxic, remain febrile, and experience tachycardia, agitation, confusion, delirium, and convulsions. Patients also may develop secondary pneumonic plague with cough, sputum, and the ability to transmit primary pulmonary plague (see later) to others.

Septicemic Plague

Septicemic plague manifests as a rapidly progressive, overwhelming endotoxemia in the absence of clinically apparent bubos. Patients often complain of gastrointestinal symptoms, including nausea, vomiting, diarrhea, and abdominal pain. Disseminated intravascular coagulation (Chapter 161) can also occur with the appearance of petechiae, ecchymoses, bleeding, and ischemia in the tips of the extremities. Later-stage septicemic (Chapter 94) patients are likely to experience refractory hypotension, renal dysfunction, obtundation, and other signs of shock. Patients with late-stage septicemic plague can also exhibit acute respiratory distress syndrome (Chapter 90), which has occasionally been confused in the American Southwest with hantaviral pulmonary syndrome (Chapter 351).

Pneumonic Plague

Pneumonic plague, which occurs 1 to 4 days after inhalation of infected droplets, can be accompanied by fever, cough, chest discomfort that becomes increasingly painful, tachycardia, dyspnea, bacteria-laden sputum, chills, headache, myalgias, weakness, and dizziness. As the illness progresses, patients may experience increasing respiratory distress, hemoptysis, cardiopulmonary insufficiency, and circulatory collapse. In the early stages of illness, patients with primary pneumonic plague may have signs of localized pulmonary involvement, beginning in a single lung and rapidly progressing to segmental consolidation and later bronchopneumonia, with death ensuing in as little as 1 to 3 days after the onset of symptoms. Localized infection is unlikely to be observed in the lungs of patients with secondary pneumonic plague because the lung tissues are infected initially through circulatory spread, which results in a diffuse interstitial pneumonitis. The appearance of sputum also differs in primary versus secondary pneumonic plague, being watery or mucoid, frothy, and perhaps tinged with blood in primary pneumonic cases but scanter, thicker, and more tenacious in secondary pneumonic cases.

DIAGNOSIS

A presumptive diagnosis of *Y. pestis* can be obtained rapidly by detecting *Y. pestis* DNA by polymerase chain reaction (PCR) assays[6] on bubo aspirates, sputum samples, or tracheal washes. Another option is a direct fluorescent antibody assay, but this procedure is generally available only through public health laboratories. Rapid immunochromatographic tests to detect plague antigen or antibodies are available in some countries, but their reliability and clinical performance are not well established, especially when testing sputum.

Laboratory confirmation currently relies on bacterial culture accompanied by specific bacteriophage lysis tests or detection of a four-fold rise in antibody titer to the *Y. pestis* F1 capsular antigen over a period of 2 to 4 weeks. Preferred laboratory samples for culture include blood, bubo aspirates, sputum, bronchoalveolar fluid, and swabs of skin lesions or pharyngeal mucosa. Cerebrospinal fluid also can be collected from patients in whom plague meningitis is suspected. Automated identification systems frequently misidentify *Y. pestis* as a different organism (e.g., *Pseudomonas luteola*, *Y. pseudotuberculosis*) and thereby delay proper diagnosis.

Differential Diagnosis

Plague fatalities are typically related to delays in seeking treatment and to misdiagnosis. The differential diagnosis of plague in its various clinical forms includes staphylococcal (Chapter 267) or streptococcal adenitis (Chapter 269) or pneumonia (Chapter 85), cat-scratch disease (Chapter 291), tularemia (Chapter 287), chancroid (Chapter 276), acute filarial lymphadenitis (Chapter 327), mycobacterial infection (Chapter 300), strangulated inguinal hernia, septicemia caused by other bacteria, meningococcemia, mycoplasma pneumonia and other community-acquired pneumonias, legionnaires disease (Chapter 290), Q fever, influenza pneumonitis (Chapter 332), hantaviral pulmonary syndrome (Chapter 351), and viral pneumonia caused by respiratory syncytial virus (Chapter 330), cytomegalovirus (Chapter 347), or other viruses.

TREATMENT

Because cases of plague can rapidly progress to a life-threatening illness, it is essential that patients with suspected plague receive appropriate empirical antimicrobial therapy immediately after samples are taken. The most commonly recommended agent for treating plague is streptomycin (see Table 288-1), but gentamicin, ciprofloxacin, and levofloxacin are also effective for treating plague in adults and children. Moxifloxacin is another first-line option for adults. Additional options include doxycycline for treating uncomplicated cases of bubonic plague and chloramphenicol[7–9] for plague meningitis. Trimethoprim-sulfamethoxazole is also an alternative option. Antimicrobial resistance has not been identified in North America, but rare instances of in vitro resistance to tetracyclines, streptomycin, and chloramphenicol have been reported from Madagascar.

TABLE 288-1 TREATMENT OF ADULTS AND CHILDREN WITH PNEUMONIC OR SEPTICEMIC PLAGUE OR BUBONIC PLAGUE* AND FOR POSTEXPOSURE PROPHYLAXIS

PATIENT CATEGORY	RECOMMENDED THERAPY
TREATMENT	
Adults	Preferred choices: Streptomycin 1 g IM twice daily Gentamicin 5 mg/kg IM or IV once daily Ciprofloxacin 400 mg IV three times daily or 750 mg PO twice daily Levofloxacin 750 mg IV or PO once daily Moxifloxacin 400 mg IV or PO once daily Alternative choices: Doxycycline 200 mg IV loading dose, then 100 mg IV or PO twice daily Chloramphenicol 12.5-25 mg/kg IV four times daily† Trimethoprim-sulfamethoxazole 5 mg/kg (trimethoprim component) three times daily IV or PO
Children§	Preferred choices: Streptomycin 15 mg/kg IM twice daily (maximum daily dose, 2 g) Gentamicin 4.5-7.5 mg/kg IM or IV once daily‖ Ciprofloxacin 10 mg/kg IV two or three times daily, or 15 mg/kg PO two or three times daily§ Levofloxacin: body weight <50 kg, 8 mg/kg IV or PO twice daily (maximum 250 mg/dose); body weight ≥50 kg, 500-750 mg IV or PO once daily Alternative choices: Doxycycline: if ≥45 kg, give adult dosage; if <45 kg, give 4.4 mg/kg loading dose then 2.2 mg/kg IV twice daily (maximum, 200 mg/day) Chloramphenicol 12.5-25 mg/kg IV four times daily† Trimethoprim-sulfamethoxazole (infants and children aged ≥2 mo to ≤17 yr): 5 mg/kg (trimethoprim component) three times daily IV or PO
Pregnant women	Preferred choice: Gentamicin *plus* either ciprofloxacin or levofloxacin Gentamicin 5 mg/kg IM or IV once daily‖ Ciprofloxacin 400 mg IV three times daily or 500 mg PO three times daily Levofloxacin 750 mg IV or PO once daily Alternative choices: Doxycycline 200 mg IV loading dose, then 100 mg IV or PO twice daily Trimethoprim-sulfamethoxazole 5 mg/kg (trimethoprim component) three times daily IV or PO
POSTEXPOSURE PROPHYLAXIS**	
Adults	Preferred choices: Doxycycline 100 mg PO twice daily†† Ciprofloxacin 500-750 mg PO twice daily Levofloxacin 500-750 mg PO once daily Moxifloxacin 400 mg PO once daily Alternative choice: Trimethoprim-sulfamethoxazole 5 mg/kg (trimethoprim component) PO twice daily
Children§	Preferred choices: Doxycycline††: if ≥45 kg, give adult dosage; if <45 kg, give 2.2 mg/kg PO twice daily Ciprofloxacin 15 mg/kg PO twice daily Levofloxacin: body weight <50 kg, 8 mg/kg PO twice daily (maximum 250 mg/dose); body weight ≥50 kg: 500-750 mg PO once daily. Alternative choice: Trimethoprim-sulfamethoxazole (infants and children ages ≥2 mo to ≤17 yr): 5 mg/kg (trimethoprim component) PO twice daily
Pregnant women	Preferred choices: Ciprofloxacin 500 mg PO three times daily or 750 mg PO twice daily Levofloxacin 750 mg PO once daily Alternative choice: Doxycycline 100 mg PO twice daily††

*Regimens are the same for all three forms of plague, with the exception that doxycycline is considered a first-line agent for patients with bubonic plague. In general, one antimicrobial agent should be selected, and therapy should be continued for 10-14 days. Oral therapy should be substituted when the patient's condition improves. Although animal and limited human studies support its use, gentamicin is not currently approved by the U.S. Food and Drug Administration (FDA) for treatment of plague in humans, nor is trimethoprim-sulfamethoxazole. Streptomycin, levofloxacin, ciprofloxacin, and moxifloxacin are FDA approved for treatment of plague. For details and additional treatment options, see reference below.

†The concentration should be maintained between 5 and 20 μg/mL. Concentrations >25 μg/mL can cause reversible bone marrow suppression.

§In children, the ciprofloxacin dose should not exceed 1 g/day.

‖Aminoglycoside dosages must be adjusted based on renal function. Evidence suggests that gentamicin 5 mg/kg intravenously or intramuscularly once daily would be efficacious in children and may reduce adverse effects. Neonates up to 1 wk of age and premature infants should receive gentamicin 2.5 mg/kg intravenously twice daily.

**The duration of treatment of plague is 10-14 days. The duration of postexposure prophylaxis to prevent plague infection is 7 days.

††Tetracycline can be substituted for doxycycline.

IM = intramuscular; IV = intravenous; PO = oral.

Adapted from Nelson CA, Meaney-Delman D, Fleck-Derderian S, et al. Antimicrobial treatment and prophylaxis of plague: recommendations for naturally acquired infections and bioterrorism response. *MMWR Recomm Rep* 2021;70:1-27.

PREVENTION

Killed whole-cell and live attenuated vaccines have limited efficacy and frequent side effects, and none are recommended or currently available in the United States. Newer recombinant vaccines designed to stimulate immune responses to the F1 and V antigens of *Y. pestis* have yielded promising results and are effective in mice, but they are not licensed for use in humans.

The risk of human plague can be reduced by surveillance programs that rapidly identify human cases or evolving epizootics and allow implementation of intervention measures. When appropriate, affected areas can be treated with insecticides to reduce the risk for flea bite exposure. Efforts also should be made to reduce the amount of food and shelter available to rodents. In rare instances, rodenticides can be used to reduce host numbers, but their use is not recommended before the implementation of effective flea control measures. Persons living in or visiting areas where plague is endemic should avoid contact with sick and dead animals and use insect repellents to reduce the risk for infectious flea bites. Dogs and cats should be prevented from roaming freely in rodent-infested areas, and these animals should be treated with flea control agents that safely and effectively kill fleas. Although most dogs appear to be somewhat resistant to plague, they can become infected and transmit infection directly to humans. Cats are

highly susceptible, often experience severe illness, and can serve as sources of infection for their owners or veterinary staff. Cats that roam outside in endemic areas and suddenly become seriously ill should be taken to a veterinarian for evaluation.

Persons with pneumonic plague should be held in respiratory isolation for at least 48 hours after the initiation of appropriate antimicrobial therapy, and individuals caring for such patients should follow respiratory droplet precautions (masks, gloves, gowns, and eye protection). Although human-to-human transmission has not been confirmed in the United States for many decades, rare cases of primary pneumonic plague have occurred after face-to-face contact with infected cats that had oral lesions or symptoms of pneumonic plague. Veterinary staff from plague-enzootic areas should take appropriate precautions (masks, gloves, gowns, eye protection) when handling sick cats with illnesses suggestive of plague.

Prophylactic antimicrobial therapy is generally recommended for persons with possible plague exposure only in relatively high-risk situations, such as after close contact with patients with pneumonic plague, handling of *Y. pestis*–infected animals, or being bitten by rodent fleas in an area with epizootic activity. The most recently recommended prophylactic antimicrobials are doxycycline, ciprofloxacin, levofloxacin, and moxifloxacin (Table 288-1).

PROGNOSIS

Patients with uncomplicated bubonic plague respond quickly to appropriate antimicrobial therapy and typically defervesce, with relief from most other systemic manifestations within 2 to 5 days. Large buboes can remain swollen, however, for more than 1 week and may require incision and drainage if necrotic. In rare instances, ischemic necrosis in septicemic cases has resulted in the amputation of digits.

The case fatality rate for plague in the United States is typically less than 15% overall and is less than 6% among patients who are treated with an effective antimicrobial. Primary pneumonic plague is nearly always fatal in the absence of prompt antimicrobial treatment. Because septicemic plague is likely to be fulminant and fatal, favorable outcomes depend on rapid diagnosis and prompt treatment with appropriate antimicrobials.

YERSINIOSIS

DEFINITION

Yersiniosis is principally an intestinal illness caused by *Yersinia enterocolitica* or *Y. pseudotuberculosis*. These enteropathogenic species differ substantially from *Y. pestis* in that they rarely cause death and are spread through the fecal-oral route.

The Pathogens

The enteropathogenic *Yersinia* are gram-negative pleomorphic bacilli that grow slowly under aerobic and anaerobic conditions and do not ferment lactose or form spores. Genetically, *Y. enterocolitica* and *Y. pseudotuberculosis* are distant from one another despite producing similar illness in humans. Unlike *Y. pestis*, both species are urease positive and motile at temperatures lower than 30° C. Unlike many Enterobacteriaceae, both species can grow at refrigerator temperatures. *Y. enterocolitica* includes diverse strains that can be divided into six biotypes (1A, 1B, 2-5) and over 70 serotypes, many of which are not human pathogens. Human illness is associated most often with bio/serotypes 1B/O:8, 4/O:3, 2/O:9, and 2,3/O:5,27. *Y. pseudotuberculosis* includes six distinct serotypes (1-6) that are pathogenic for humans.

EPIDEMIOLOGY

Enteropathogenic yersiniae are transmitted by contaminated food and water and occasionally by contact with infected persons or animals. Rare but serious infections have resulted from transfusion of blood from an infected donor. The oral infectious dose is thought to be relatively large, between 10^5 and 10^9 bacteria. *Y. enterocolitica* infection, which accounts for 80 to 90% of cases in most countries, is strongly associated with consumption of contaminated pork products. This route reflects the organism's affinity for colonizing the tonsils of healthy swine. Other species including rabbits, hares, sheep, goats, cattle, rodents, and dogs can harbor pathogenic strains and serve as sources of human infection, either directly or by contamination of milk or produce.

Yersinia pseudotuberculosis, which is also found in a wide range of animals, causes illness and epizootics, particularly among hares and rabbits. Although sources of human infection are less well defined, outbreaks of *Y. pseudotuberculosis* infection in Northern Europe have been linked to stored produce, especially root vegetables and lettuce. Consumption of carrots and lettuce was also identified as a risk factor in an unusually large New Zealand outbreak in 2014. Milk has been implicated as a source for *Y. pseudotuberculosis* outbreaks, as has contact with kittens and puppies.

Yersiniosis occurs worldwide but is generally more common in cooler, temperate regions. Annual rates of reported illness range widely from less than 1 per 100,000 population in parts of southern Europe to more than 20 per 100,000 population in New Zealand.[10] Countries with historically higher rates include the Scandinavian countries, Germany, and Belgium. Dietary practices likely play a role in these high rates, as well as in the apparent rarity of yersinosis in predominantly Muslim countries where pork consumption is discouraged. Bio/serotype 4/O:3, which is found commonly in swine, predominates in most countries. The second most common bio/serotype, 2/O:9, is typically isolated from sheep, cows, and goats. Human infections with *Y. pseudotuberculosis* are most commonly reported in northern Europe and in Asia, including Japan.

In the United States, the reported incidence as determined by culture is approximately 0.4 cases per 100,000. However, when considering results from culture-independent testing, which has become more common in recent years, the incidence in 2021 was 1.4 cases per 100,000 population.[11] From 2015 to 2020, the incidence was highest among adults over age 65 years, at nearly 1.9 cases per 100,000 population, and the peak onset was in the summer months. In the United States, rates are now highest in Whites and lowest in Blacks. Asian and Pacific Islanders have the second highest incidence, slightly lower than that of Whites. Rates among Hispanics are approximately one third that of non-Hispanics.

Transmission by blood transfusion is thought to result from occult bacteremia in donors combined with the bacterium's ability to multiply in blood stored at cold temperatures. Dozens of such cases have been reported, many fatal.

PATHOBIOLOGY

Nearly all pathogenic *Yersinia* share an approximately 70-kb plasmid that encodes key virulence factors. Principal among these are an adhesin, YadA, and a type III secretion system that injects host cells with effector proteins that blunt the immune response and can trigger apoptosis.[12] YadA works in conjunction with chromosomally encoded proteins to promote epithelial cell attachment, host cell invasion, and complement resistance. The pathogenic potential of common *Y. enterocolitica* serotypes is blunted by their limited ability to acquire iron; which may explain their enhanced virulence in hosts with iron-overload syndromes. In contrast, the genomes of *Y. enterocolitica* 1B/O:8 and pathogenic *Y. pseudotuberculosis* include a high pathogenicity island, which encodes a siderophore that enhances the acquisition of iron from the environment and thus virulence. *Y. enterocolitica* also produces a heat-stable enterotoxin, Yst, but its role in pathogensis remains uncertain. Strains of *Y. pseudotuberculosis* from Asia are notable for their production of a superantigen, YPMa, which is implicated in Far East scarlet-like fever syndrome.

Following ingestion, enteropathogenic *Yersinia* penetrate the mucus layer and adhere to mucosal epithelial cells. Areas of the terminal ilium and proximal cecum appear particularly susceptible, though colonization of the tonsils also occurs and can cause pharyngitis. Following attachment, intestinal M cells translocate the pathogen into adjacent Peyer patches, where they can replicate. Spread to mesenteric lymph nodes produces an inflammatory response, mesenteric adenitis, and abdominal pain. Further dissemination may lead to the formation of microabscesses in the liver and spleen.

CLINICAL MANIFESTATIONS

After an incubation period of 3 to 7 days, yersiniosis typically presents as acute enteritis or mesenteric adenitis. Young children are more likely to have fever and diarrhea, which may be bloody and difficult to distinguish from gastroenteritis caused by *Salmonella* (Chapter 284) or *Campylobacter* (Chapter 279). In teenagers and young adults, symptoms of mesenteric adenitis and terminal ileitis are more common and can mimic appendicitis (Chapter 128)[13] with fever and right lower quadrant pain. Abdominal computed tomography (CT) showing mesenteric adenitis with a normal appendix suggests the diagnosis. Pharyngitis occurs in up to 20% of patients and is a diagnostic clue because other infectious enteritidies lack this feature.

Sepsis and metastatic infection are uncommon but a serious threat in patients with underlying conditions. Medical conditions associated with iron overload (e.g., hemochromatosis, thalassemia, cirrhosis) or its treatment (deferoxamine) greatly increase the risk of infection and complications.[14] Other conditions including HIV infection, diabetes, and older age also increase risk. Metastatic spread of infection can result in osteomyelitis, septic arthritis, endocarditis,[15] mycotic aneurysms, ophthalmitis, and meningitis. Although relatively rare, infection by transfusion can result in overwhelming sepsis and shock.

Yersiniosis is remarkable for several extraintestinal complications. Reactive arthritis (Chapter 254), occasionally with uveitis and urethritis, is well described, especially in patients who are positive for the human leukocyte antigen (HLA)-B27. Oligoarticular joint symptoms appear 1 to 3 weeks after infection, most often in the lower extremities. Erythema nodosum is also relatively common, especially among women. Thought to be a form of delayed hypersensitivity, symptoms of erythema nodosum usually begin 2 weeks after onset of gastroenteritis. Rare complications, presumably immunologically mediated, include glomerulonephritis and myocarditis. Rare reports also suggest an association between *Y. pseudotuberculosis* and Kawasaki disease (Chapter 249).

DIAGNOSIS

Yersiniosis should be suspected in patients who have abdominal pain and fever, with or without frank diarrhea. The diagnosis is best accomplished by identifying the bacterium from stool, blood, or other appropriate samples. Culture-independent methods are increasingly common, and PCR or other DNA-based methods are likely to result in more rapid and sensitive detection of these bacteria.[16]

Culture of *Y. enterocolitica* and *Y. pseudotuberculosis* from stool and environmental samples is complicated by the presence of other, faster-growing bacteria in the sample. Biotyping and serotyping, which are often available only in research or public health reference laboratories, can provide useful epidemiologic information.

Tube or microagglutination tests also can identify antibodies to the pathogenic *Y. enterocolitica* serogroups O:3, O:9, O:5,27, and O:8, but cross-reactivity can be a problem, particularly between *Y. enterocolitica* O:9 and *Brucella* spp. Immunologically mediated *Yersinia* illnesses, including reactive arthritis, are associated with the production of immunoglobulin (Ig) antibodies that can be detected by enzyme-linked immunosorbent assay (ELISA) or immunoblotting. IgG antibodies can persist for many years, but persistence of IgA antibodies for more than a few months could indicate a chronic *Yersinia* infection.

TREATMENT

Antimicrobial therapy has not been shown to improve the course of uncomplicated enterocolitis or mesenteric adenitis and is not generally recommended for intestinal forms of the disease. There also is no evidence that antimicrobial treatment reduces the frequency of reactive arthritis or erythema nodosum.

Antimicrobial therapy is recommended, however, for immunocompromised patients, patients with septicemia, and patients with systemic disease or extraintestinal foci of infection. Recommended agents for treatment of sepsis or other severe forms of disease are standard dosages of an aminoglycoside (e.g., gentamicin, 5 mg/kg per day in one to three divided doses) combined with either a third-generation cephalosporin (e.g., ceftriaxone, 2 g per day) or with ciprofloxacin (400 mg IV two to three times daily; all adult dosages). Duration of therapy is poorly defined, but 2 to 3 weeks has proven successful in retrospective series. Emerging resistance to the quinolones has been observed in some countries; and the choice of definitive therapy should be guided by susceptibility testing.

PREVENTION

Vaccines are not currently available. Prevention depends on basic sanitation measures. These include using proper sewage disposal methods, protecting water supplies from contamination with human or animal waste, following appropriate procedures for animal husbandry and slaughtering, thoroughly cooking meats (especially pork), avoiding long-term storage of meats at temperatures higher than 4° C, and consuming only pasteurized milk. Food handlers should thoroughly wash their hands before and after handling potentially contaminated foods, especially pork intestines. Persons with diarrhea should not work in food-handling areas, care for young children, or work with patients, and hospital staff should follow enteric precautions.

PROGNOSIS

Yersiniosis is generally self-limited after a 2- to 3-week course of illness in most healthy individuals, but patients with underlying conditions may experience life-threatening sepsis or metastatic infection. Patients often shed the organism in stool while symptomatic and potentially for up to several months following recovery.

Sequelae most commonly include erythema nodosum, which generally resolves within 1 month, and reactive arthritis, which generally resolves within 6 months. Other sequelae can include endocarditis, pericarditis, and osteomyelitis. As with many other infectious agents, enteropathogenic *Yersinia* has been implicated in the pathogenesis of autoimmune thyroid disease,[17] though a definitive role has not been established.

WHOOPING COUGH AND OTHER *BORDETELLA* INFECTIONS

CHRISTOPHER J. GILL AND ERIK L. HEWLETT

DEFINITION

Whooping cough, also known as pertussis, is a toxin-mediated, highly contagious respiratory illness that affects all age groups and is characterized by distinctive, violent, paroxysmal coughing episodes, which end in the classic inspiratory whoop that gives the disease its name. Each paroxysm may last several minutes, and patients often feel entirely normal between paroxysms. Severe and fatal disease is concentrated among infants, in whom pertussis may be manifested by spells of apnea and cyanosis, alone or in conjunction with coughing. Whooping cough is primarily caused by infection with *Bordetella pertussis* or, much less frequently, *Bordetella parapertussis* or *Bordetella bronchiseptica*.

The Pathogens

Bordetellae are gram-negative coccobacilli, many of which are motile under specific conditions. Sixteen known species of *Bordetella* include the classic species of *B. pertussis*,[1] *B. parapertussis*, and *B. bronchiseptica*, which is primarily a veterinary pathogen. *B. holmesii* is a cause of pulmonary infections and mild whooping cough–like illness, as well as invasive tissue infections. Other *Bordetella* species (E-Table 289-1) are associated with bacteremia and wound infections in patients with comorbid, immune-compromising conditions, such as diabetes, cancer/chemotherapy, or chronic cholangitis. *B. avium* (primarily a pathogen for turkeys and other poultry) and *B. hinzii* can cause difficult-to-treat nosocomial infections, principally sepsis and ventilator-associated pneumonias. Additional bordetellae are present in soil, but little is known about their ability to cause disease in humans.

EPIDEMIOLOGY

Historically, pertussis was a childhood illness. Although children below 1 year of age are at the highest risk of death, more than 50% of cases in the United States now occur in individuals over 10 years of age. However, reported cases likely represent only 5 to 10% of total cases, and the population burden of disease is uncertain. The first-generation whole-cell pertussis vaccines, beginning in the 1940s, reduced total cases by 99% and also shifted the age distribution of disease to adolescents and adults. In unvaccinated populations, pertussis was contracted throughout childhood; although the resultant immunity was not lifelong, continued exposure to pertussis in the population allowed such unvaccinated individuals to reinforce their immunity with little or no subsequent clinical disease. The introduction of acellular pertussis vaccines for infants and children resulted in a marked reduction of disease, except in infants too young to have acquired immunity from vaccination, but the incidence of pertussis increased relatively and absolutely in adolescents and adults, partly due to the relatively brief duration of protection offered by the acellular vaccines, with failure rates approaching 50% after 2 to 3 years.

Beginning in the 1990s, the transition from whole-cell products to acellular pertussis vaccines in response to concerns about the safety of the former contributed to major increases in pertussis, which is now resurgent in the United States and elsewhere in the world. About 20,000 cases of pertussis are now reported annually in the United States, and approximately 60% of these cases are in adolescents and adults.[2] Some of these cases are detected by polymerase chain reaction (PCR) testing only, which explains an increase

Yersiniosis is remarkable for several extraintestinal complications. Reactive arthritis (Chapter 254), occasionally with uveitis and urethritis, is well described, especially in patients who are positive for the human leukocyte antigen (HLA)-B27. Oligoarticular joint symptoms appear 1 to 3 weeks after infection, most often in the lower extremities. Erythema nodosum is also relatively common, especially among women. Thought to be a form of delayed hypersensitivity, symptoms of erythema nodosum usually begin 2 weeks after onset of gastroenteritis. Rare complications, presumably immunologically mediated, include glomerulonephritis and myocarditis. Rare reports also suggest an association between *Y. pseudotuberculosis* and Kawasaki disease (Chapter 249).

DIAGNOSIS

Yersiniosis should be suspected in patients who have abdominal pain and fever, with or without frank diarrhea. The diagnosis is best accomplished by identifying the bacterium from stool, blood, or other appropriate samples. Culture-independent methods are increasingly common, and PCR or other DNA-based methods are likely to result in more rapid and sensitive detection of these bacteria.[16]

Culture of *Y. enterocolitica* and *Y. pseudotuberculosis* from stool and environmental samples is complicated by the presence of other, faster-growing bacteria in the sample. Biotyping and serotyping, which are often available only in research or public health reference laboratories, can provide useful epidemiologic information.

Tube or microagglutination tests also can identify antibodies to the pathogenic *Y. enterocolitica* serogroups O:3, O:9, O:5,27, and O:8, but cross-reactivity can be a problem, particularly between *Y. enterocolitica* O:9 and *Brucella* spp. Immunologically mediated *Yersinia* illnesses, including reactive arthritis, are associated with the production of immunoglobulin (Ig) antibodies that can be detected by enzyme-linked immunosorbent assay (ELISA) or immunoblotting. IgG antibodies can persist for many years, but persistence of IgA antibodies for more than a few months could indicate a chronic *Yersinia* infection.

TREATMENT

Antimicrobial therapy has not been shown to improve the course of uncomplicated enterocolitis or mesenteric adenitis and is not generally recommended for intestinal forms of the disease. There also is no evidence that antimicrobial treatment reduces the frequency of reactive arthritis or erythema nodosum.

Antimicrobial therapy is recommended, however, for immunocompromised patients, patients with septicemia, and patients with systemic disease or extraintestinal foci of infection. Recommended agents for treatment of sepsis or other severe forms of disease are standard dosages of an aminoglycoside (e.g., gentamicin, 5 mg/kg per day in one to three divided doses) combined with either a third-generation cephalosporin (e.g., ceftriaxone, 2 g per day) or with ciprofloxacin (400 mg IV two to three times daily; all adult dosages). Duration of therapy is poorly defined, but 2 to 3 weeks has proven successful in retrospective series. Emerging resistance to the quinolones has been observed in some countries; and the choice of definitive therapy should be guided by susceptibility testing.

PREVENTION

Vaccines are not currently available. Prevention depends on basic sanitation measures. These include using proper sewage disposal methods, protecting water supplies from contamination with human or animal waste, following appropriate procedures for animal husbandry and slaughtering, thoroughly cooking meats (especially pork), avoiding long-term storage of meats at temperatures higher than 4° C, and consuming only pasteurized milk. Food handlers should thoroughly wash their hands before and after handling potentially contaminated foods, especially pork intestines. Persons with diarrhea should not work in food-handling areas, care for young children, or work with patients, and hospital staff should follow enteric precautions.

PROGNOSIS

Yersiniosis is generally self-limited after a 2- to 3-week course of illness in most healthy individuals, but patients with underlying conditions may experience life-threatening sepsis or metastatic infection. Patients often shed the organism in stool while symptomatic and potentially for up to several months following recovery.

Sequelae most commonly include erythema nodosum, which generally resolves within 1 month, and reactive arthritis, which generally resolves within 6 months. Other sequelae can include endocarditis, pericarditis, and osteomyelitis. As with many other infectious agents, enteropathogenic *Yersinia* has been implicated in the pathogenesis of autoimmune thyroid disease,[17] though a definitive role has not been established.

WHOOPING COUGH AND OTHER *BORDETELLA* INFECTIONS

CHRISTOPHER J. GILL AND ERIK L. HEWLETT

DEFINITION

Whooping cough, also known as pertussis, is a toxin-mediated, highly contagious respiratory illness that affects all age groups and is characterized by distinctive, violent, paroxysmal coughing episodes, which end in the classic inspiratory whoop that gives the disease its name. Each paroxysm may last several minutes, and patients often feel entirely normal between paroxysms. Severe and fatal disease is concentrated among infants, in whom pertussis may be manifested by spells of apnea and cyanosis, alone or in conjunction with coughing. Whooping cough is primarily caused by infection with *Bordetella pertussis* or, much less frequently, *Bordetella parapertussis* or *Bordetella bronchiseptica*.

The Pathogens

Bordetellae are gram-negative coccobacilli, many of which are motile under specific conditions. Sixteen known species of *Bordetella* include the classic species of *B. pertussis*,[1] *B. parapertussis*, and *B. bronchiseptica*, which is primarily a veterinary pathogen. *B. holmesii* is a cause of pulmonary infections and mild whooping cough–like illness, as well as invasive tissue infections. Other *Bordetella* species (E-Table 289-1) are associated with bacteremia and wound infections in patients with comorbid, immune-compromising conditions, such as diabetes, cancer/chemotherapy, or chronic cholangitis. *B. avium* (primarily a pathogen for turkeys and other poultry) and *B. hinzii* can cause difficult-to-treat nosocomial infections, principally sepsis and ventilator-associated pneumonias. Additional bordetellae are present in soil, but little is known about their ability to cause disease in humans.

EPIDEMIOLOGY

Historically, pertussis was a childhood illness. Although children below 1 year of age are at the highest risk of death, more than 50% of cases in the United States now occur in individuals over 10 years of age. However, reported cases likely represent only 5 to 10% of total cases, and the population burden of disease is uncertain. The first-generation whole-cell pertussis vaccines, beginning in the 1940s, reduced total cases by 99% and also shifted the age distribution of disease to adolescents and adults. In unvaccinated populations, pertussis was contracted throughout childhood; although the resultant immunity was not lifelong, continued exposure to pertussis in the population allowed such unvaccinated individuals to reinforce their immunity with little or no subsequent clinical disease. The introduction of acellular pertussis vaccines for infants and children resulted in a marked reduction of disease, except in infants too young to have acquired immunity from vaccination, but the incidence of pertussis increased relatively and absolutely in adolescents and adults, partly due to the relatively brief duration of protection offered by the acellular vaccines, with failure rates approaching 50% after 2 to 3 years.

Beginning in the 1990s, the transition from whole-cell products to acellular pertussis vaccines in response to concerns about the safety of the former contributed to major increases in pertussis, which is now resurgent in the United States and elsewhere in the world. About 20,000 cases of pertussis are now reported annually in the United States, and approximately 60% of these cases are in adolescents and adults.[2] Some of these cases are detected by polymerase chain reaction (PCR) testing only, which explains an increase

ABSTRACT

Whooping cough, also known as "pertussis," is a respiratory illness that affects all age groups and is characterized by distinctive, violent, paroxysmal coughing that is followed by gasping inhalation to produce the eponymous "whooping" sound. Pertussis is resurgent in the United States and elsewhere in the world, and vaccine practices have shifted the age-specific incidence of the disease from infants to adolescents and adults. Individuals also can be contagious asymptomatic "carriers." The paroxysmal stage can last several weeks or even months, during which adults seek medical care for chronic cough. Diagnosis by polymerase chain reaction–based tests or by culture have limitations. Antibiotics do not provide symptomatic relief or alter the course of the illness, but they are used because affected individuals can remain culture positive and potentially transmit *Bordetella pertussis* for several weeks after the onset of symptoms. Continued progress in vaccine development is likely to alter vaccination practices.

E-TABLE 289-1 CHARACTERISTIC FEATURES OF *BORDETELLA* SPECIES

BORDETELLA SPECIES	PRIMARY HOST	PRIMARY SYNDROME	OCCASIONAL SYNDROMES	ROLE OF HOST IMMUNE STATUS		FREQUENCY	TREATMENT	COMMENTS
				NORMAL HEALTHY	IMMUNOCOMPROMIED			
B. pertussis	Humans	Whooping cough	Pneumonia	X		Common	First line: Macrolides Second line: Sulfonamides quinolones Resistant to cephalosporins and penicillins	Highest mortality in young infants. Disease largely mediated by toxins rather than tissue invasion. True burden of disease is likely underestimated.
B. parapertussis	Humans (separate lineage is pathogen for sheep)	Whooping cough (milder than *B. pertussis*)		X		Common	Same as for *B. pertussis*	Similar to pertussis, though milder illness. Carries pertussis toxin gene but does not express it in vivo. Easily missed if using PCR probing for IS481 to screen for *B. pertussis*.
B. holmesii	Humans, possibly birds	Whooping cough (milder than *B. pertussis*)	Pneumonia, bacteremia, endocarditis, septic arthritis	X	X	Common	First line: Quinolones Second line: Macrolides, sulfonamides, carbapenems Resistant to cephalosporins and penicillins	Similar to pertussis but milder and with higher propensity for nonpulmonary disease. Often misclassified as pertussis due to expression of IS481. Most microbiology laboratories are unable to distinguish *B. pertussis* from *B. holmesii*. More susceptible to first-generation cephalosporins and less to macrolides than *B. pertussis*.
B. bronchiseptica	Dogs (kennel cough), pigs, cats, rabbits	Whooping cough (mild)	Pneumonia		X	Rare	First line: Quinolones, tetracyclines, aminoglycosides, and anti-pseudomonal penicillins Generally resistant to macrolides; variable resistance to sulfonamides	Mild disease
B. trematum	Unknown, probably birds	Wound infections			X	Extremely rare	Insufficient data	Identified in wound infections and patients with chronic otitis media. Genetically very similar to *B. avium*, found in birds.
B. ansorpii	Unknown	Bacteremia			X	Extremely rare	Insufficient data	Two case reports only, both in patients undergoing chemotherapy (sarcoma and leukemia)
B. avium	Turkeys, other birds	Chronic and ventilator pneumonias			X	Extremely rare	Insufficient data	Identified in patients with cystic fibrosis in one case series. Formally a subtype of *Alcaligenes faecalis*.
B. hinzii	Unknown	Bacteremia, ventilator pneumonias			X	Extremely rare	Insufficient data	Most cases identified in patients with severe chronic medical illnesses or cancers. Formally a subtype of *A. faecalis*.
B. petrii	Unknown	Bacteremia			X	Extremely rare	Insufficient data	Most recently identified species; case report in a patient with mandibular osteosarcoma

in the detection of milder and atypical cases. Nevertheless, severe and fatal disease in infants has also increased, thereby suggesting the overall increased burden of disease is real and not an artifact of detection bias.

Pertussis remains endemic even in countries with high rates of vaccination,[3] with spikes in reported cases occurring in the United States in 3- to 5-year cycles, an interval that is postulated to reflect the accumulation of susceptible individuals in the population. The fact that whole-cell pertussis vaccines resulted in a longer interepidemic cycle time strongly suggests that they were more effective than acellular vaccines for interfering with person-to-person transmission, as well as preventing clinical disease. Animal data also indicate that both whole-cell and acellular vaccines block symptomatic disease, but whole-cell vaccines also reduce the density and duration of mucosal carriage, thereby impeding person-to-person spread. Furthermore, infant baboons who have received acellular vaccines remain contagious and easily spread their infection to unvaccinated cage mates.

Worldwide, pertussis continues to be a major problem not only in developed countries with vaccine programs, especially for individuals with chronic health conditions,[4,5] but also in developing countries.[6] For example, Zambia, Pakistan, and South Africa have had ongoing transmission of pertussis. Fortunately, most detected cases were clinically mild and did not progress to classic pertussis, thereby suggesting that the existing vaccine programs are preventing severe disease but not all transmission.

Although *B. pertussis* is a relatively fastidious organism that is not easily cultured, pertussis is a highly contagious infection, with spread believed to be primarily by aerosol droplets from both symptomatic and asymptomatic hosts. Transmission by asymptomatic hosts occurs frequently in adults and in infants, in whom asymptomatic infections are far more common than symptomatic infections.[7]

PATHOBIOLOGY

Pertussis usually is not a tissue-invasive disease; rather, its pathogenesis is mediated indirectly through its toxins acting in situ or, in the case of pertussis toxin, systemically. *B. pertussis* and related organisms produce a number of toxins, and interdiction of pertussis toxin, as, for example, by vaccines that target pertussis toxin can prevent severe disease.[8] The precise molecular mechanisms underlying the classic paroxysmal cough still have not been identified, but bradykinin-induced inflammation and pertussis toxin–mediated interference with the anti-inflammatory effects of sphingosine-1-phosphate[9] appear to be contributing factors.

Knowledge about the toxins and adhesins is important both for their potential roles in pathogenesis and for their use as antigens in acellular pertussis vaccines. Filamentous hemagglutinin,[10] pertactin, and fimbriae are adhesins that are components in most of the acellular vaccines, and all currently available vaccines include pertussis toxoid. Pertussis toxin is a soluble toxin with local and systemic effects, including direct induction of leuko-lymphocytosis and enhancement of glucose-stimulated insulin secretion, both of which may contribute to the pertussis syndrome. Pertussis toxin also has an immunomodulatory effect that promotes prolonged survival of *B. pertussis* in the respiratory tract. Early in disease, pertussis toxin downregulates immune responses and likely perpetuates infection by inhibiting alveolar macrophages on mucosal surfaces and interfering with the recruitment of neutrophils. Later in the disease, pertussis toxin upregulates inflammatory responses, perhaps as a mechanism to enhance shedding and infectivity. Adenylate cyclase toxin binds to CR3 to enter host cells and produce supraphysiologic levels of cyclic adenosine monophosphate (cAMP). The antibacterial functions of macrophages and neutrophils are inhibited by the increased cAMP, thereby leading to limited immunosuppression, which likely enhances the survival of *B. pertussis*.

Bacteria adherent to the cilia cause damage to respiratory epithelial cells, some of which are lost from the mucosa. Mucus secretion is prominent, especially during later stages of the illness. Intracellular *B. pertussis* organisms have been demonstrated, but their significance remains unknown.

CLINICAL MANIFESTATIONS

Following exposure to a patient with active pertussis, typically by aerosol from coughing or sneezing but also likely through asymptomatic chains of transmission, an infected individual will experience an onset of nonspecific upper respiratory symptoms (mainly coryza) about 1 to almost 3 weeks later. Clinical signs that indicate onset of the catarrhal phase (rhinorrhea, increased lacrimation, conjunctival injection, and sometimes low-grade fever) are nonspecific and may be self-resolving. Furthermore, clinically trivial or asymptomatic infections occur commonly,[11] particularly in adults and to a lesser degree in infants, thereby suggesting that asymptomatic adults may be responsible for a substantial fraction of overall transmissions.

Although the classic paroxysmal cough of pertussis is striking and unforgettable, not all symptomatic children or adults experience it.[12] The diagnosis of pertussis often is not even considered until a patient manifests the striking cough, which consists of a series of uncontrollable expirations, followed by gasping inhalation that is responsible for the "whooping" sound. Episodes of coughing can be associated with cyanosis and end with gagging and vomiting. Eighty percent or more of adolescents and adults with classic pertussis have paroxysmal cough, but the frequency of whoop and post-tussive vomiting is variable.[13] This paroxysmal stage can persist more than 4 weeks, and the development of fever or worsening pulmonary function during this time suggests the possibility of secondary bacterial pneumonia. During the paroxysmal stage, adults may experience atypical symptoms, such as a scratchy throat and episodes of sweating.

A reduction in the frequency and severity of coughing marks the transition to the convalescent phase, which can persist several months. It is often during this time that adults present to the health care system with a chronic cough (Chapter 71) and may be evaluated for conditions such as asthma (Chapter 75), tuberculosis (Chapter 299), other chronic lung diseases, malignancies, and gastroesophageal reflux (Chapter 124). After the cough appears to have ended, patients may experience return of paroxysmal cough in conjunction with an unrelated upper respiratory illness, which is often incorrectly interpreted as a recurrence of pertussis.

Although *B. pertussis* and *B. parapertussis* can rarely cause bacteremia, infections with these organisms are principally localized to the respiratory tract.

Complications

In infants and children younger than age 5 years with severe pertussis, hospitalization is common; 5 to 10% have pneumonia, nearly 1% of infants experience seizures, and encephalopathy is seen in 0.1%. Adolescents and adults have these same complications with lower frequency,[14] but the severe cough can sometimes cause cough syncope (Chapter 49), a herniated intervertebral disc (Chapter 369), sudden-onset hearing loss (Chapter 396), episodes of angina (Chapter 56), and even carotid artery dissection (Chapter 376). The paroxysmal cough and associated post-tussive vomiting can be severe and protracted enough to cause rib fractures, muscle injuries, conjunctival hemorrhages, and other forms of tissue trauma.

DIAGNOSIS

Although pertussis can have a classic clinical presentation, milder presentations may be indistinguishable from other common respiratory infections.[15] PCR-based diagnostic tests, which are sensitive and can remain positive for several days or weeks into antimicrobial treatment, can distinguish *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica*. Culture of the nasopharynx has a sensitivity of only about 50% and is even lower if antimicrobial treatment has been initiated before the specimen was collected. Detection of serum antibodies to products of *B. pertussis* can identify patients late in infection, but care must be taken to distinguish an acute response from residual antibodies to vaccine or nonvaccine antigens.

In resource-limited settings, a clinical case definition for the diagnosis of pertussis is 21 or more days of paroxysmal coughing with laboratory confirmation or epidemiologic linkage. However, this definition misses cases of lesser severity or shorter duration, as well as asymptomatic cases. Adults with preexisting asthma or chronic obstructive pulmonary disease are about twice as likely to be diagnosed with clinical pertussis.[16] Diagnosis of the very rare environmental and nonrespiratory *Bordetellae* is difficult outside of research settings, and no standardized diagnostic tests exist.

TREATMENT

Supportive Therapy

For infants, young children, and seriously ill adults, supportive therapy is often the most important component of medical care. Close observation is essential to ensure adequate nutrition, oxygenation, and hydration. After onset of paroxysmal cough, neither antibiotics nor other pharmacologic interventions are effective for ameliorating the cough.

Antimicrobial Agents

Since pertussis is a toxin-mediated disease and since the biologic effects of the toxins can persist even after the bacteria have been eradicated, antimicrobial agents may not offer much symptomatic relief or alter the course of illness unless initiated within the first week of symptoms, well before onset of paroxysmal cough. However, treatment is important to limit transmission to other individuals.

The recommended treatments of pertussis in adults are azithromycin (500 mg on day 1, followed by 250 mg/day on days 2 to 5), clarithromycin (1 g/day in two divided doses for 7 days), erythromycin (2 g/day in four divided doses for 7 days), or trimethoprim/sulfamethoxazole (trimethoprim 320 mg/day, sulfamethoxazole 1600 mg/day in two divided doses for 14 days). For parapertussis, *B. holmesii*, and *B. bronchiseptica*, treatment is as for pertussis. Resistance to macrolide antibiotics is extremely common in some parts of China but not currently in other locales.[17]

PREVENTION

Immunization

Killed, whole-cell pertussis vaccines, which became widely used in the United States, reduced reported cases of pertussis from more than 200,000 annually to less than 2000 in 1980. However, concerns about side effects led to the switch to acellular pertussis vaccines, which cause significantly fewer adverse reactions but lose effectiveness after 2 to 3 years and have very limited ability to block person-to-person transmission of the pathogen.[A1]

In the United States, infants typically receive DTaP (diphtheria, tetanus, acellular pertussis), administered with inactivated polio vaccine and either hepatitis B vaccine or *Haemophilus influenzae* type B vaccine (Chapter 15). Booster vaccines (i.e., Tdap, where the capitalized T represents full-dose tetanus, and the lowercase "d" and "ap" refer to reduced-dose diphtheria and acellular pertussis, respectively) are recommended starting at age 11 years. Outside of the United States, whole-cell pertussis vaccines are similarly combined with other common injectable antigens in various combinations, including diphtheria, tetanus, and either *H. influenzae* type B or hepatitis B.

By 5 to 10 years after introduction of acellular pertussis vaccines, which elicit a shorter duration of immunologic protection compared with whole-cell vaccines, rates of clinical disease began to climb, reaching about 20,000 cases per year in the United States, though with significant year-to-year variation. Part of the problem may be a steady accumulation of *B. pertussis* strains that no longer express one or more of the virulence factors used as acellular vaccine antigens, presumably as an evolutionary response.

In addition, although both whole-cell and acellular pertussis vaccines are effective at preventing clinical illness, whole-cell vaccines abbreviate the duration of infection and reduce bacterial loads in the nasopharynx, whereas acellular vaccines have no impact on either the duration of colonization or the bacterial load. Consequently, recipients of acellular vaccine can infect others and perpetuate outbreaks, thereby undermining the strategy of vaccinating the household contacts of a newborn to prevent spread to the infant, a practice commonly referred to as "cocooning."

By contrast, maternal Tdap given later in pregnancy augments infants' passive IgG-mediated immunity to pertussis and is highly effective at reducing infant pertussis. Although such passive immunity is transient, it creates a bridge through the first 3 months of life, when infants are most vulnerable to severe pertussis and when pertussis deaths are concentrated. As a result, it is now recommended routinely in the United States for all pregnant women.

Candidate third-generation pertussis vaccines being tested in humans include a live-attenuated nasal vaccine designed to optimize local mucosal immune responses and a polysaccharide-protein conjugate vaccine linking *B. pertussis* capsule to pertussis toxin.[18] The emerging consensus is that the next generation of pertussis vaccines must block person-to-person spread by sterilizing mucosal immunity.

Chemoprophylaxis

Chemoprophylaxis with 5 days of azithromycin (500 mg on day 1, then 250 mg on days 2 to 5) is an important mechanism for controlling outbreaks in hospitals or the community. This approach is highly effective when initiated before the onset of symptoms but much less effective if started more than 14 days after the onset of symptoms in the index case.[19] Chemoprophylaxis is recommended for individuals exposed within the preceding 3 weeks, high-risk persons with underlying health problems, infants, other individuals who have not been immunized, and recently exposed individuals who have frequent occupational or other contact with susceptible hosts.

PROGNOSIS

Most patients will eventually clear *B. pertussis*, even without antimicrobial treatment, but 80% of adults with pertussis have an illness of at least 3 weeks' duration, and about 25% are still coughing after 90 days. Antimicrobial agents do not alter the course, and symptoms persist well beyond elimination of the causal organism. In contrast, infections with *B. bronchiseptica* are often long-lasting and require antibiotic treatment for clearance.

290 *LEGIONELLA* INFECTIONS

JONAS MARSCHALL AND VICTORIA J. FRASER

DEFINITION

Legionellosis refers to two clinical syndromes caused by *Legionella* bacteria: pneumonia and Pontiac fever. *Legionella* pneumonia (legionnaires disease) can be episodic or occur in outbreaks, and it can be acquired in the community or in health care settings. Pontiac fever is an acute, self-limited febrile illness caused by inhalation or aspiration of *Legionella* spp. *Legionella* extrapulmonary infections include meningitis, cellulitis, and skin and soft tissue abscesses. Endocarditis and wound infections also rarely occur.

The Pathogen

Legionellae are slender, noncapsulated, non-spore forming, obligatory aerobic, nutritionally fastidious, pleomorphic gram-negative bacilli (0.3-0.9 μm wide by 2-20 μm long) that belong to the Legionellaceae family (E-Fig. 290-1A to 1D). *Legionella* are facultative intracellular pathogens. *L. pneumophila* have a single polar flagellum. *L. longbeachae* differ in that they do not have a flagellum but have a capsule. *Legionella* spp. stain poorly on Gram stain. Warthin-Starry or Dieterle stains can demonstrate organisms in tissue. *L micdadei* and some other *Legionella* spp. may stain weakly acid-fast.

Legionella spp. have genomes that range in size from 2.37 to 4.88 Mb, but the core genome is comprised of only 1008 genes (6%). Recombination plays an important role in the organism's evolution and likely accounts for the development of new virulent strains as well as strains adapted to surviving in man-made water systems.[1]

EPIDEMIOLOGY

The Legionellaceae family has more than 60 species with more than 70 serogroups. *L. pneumophila*, which accounts for up to 90% of human infections, has more than 15 serogroups. Serogroup 1 is the most common cause of human infections, followed by serogroups 3, 4, and 6, although all groups can infect humans. *L. longbeachae*, which is more virulent than *L. pneumophila*, is the second most common species causing human disease, particularly in Australia and New Zealand. More than 25 *Legionella* spp. including: *L. micdadei, L. bozemanae, L. feeleii, L. anisa,* and *L. dumoffii* have been reported to cause human disease.

Legionella spp. are present in the environment worldwide. *L. pneumophila* and most *Legionella* spp. live in streams and lakes, and they thrive in man-made indoor and outdoor water systems, including drinking water, hot water pipes, fountains, air conditioning systems, and cooling towers. Almost all cases of legionnaires disease are due to exposure from *Legionella* contamination of man-made water sources.[2] *Legionella* can live either freely or as intracellular parasites in a number of different protozoans including *Acanthamoeba* and *Hartmannella* species (E-Fig. 290-1E). Growth of *Legionella* is promoted by warm temperatures, stagnation, and the presence of sediment in water systems. *Legionella* can withstand temperatures of 32 to 154° F (0 to 68° C), and they form biofilms that help them resist chlorination. The reservoir of *L. longbeachae* is in soil, including potting soil and compost, in contrast to other *Legionella*, which are more commonly found in water.

The recommended treatments of pertussis in adults are azithromycin (500 mg on day 1, followed by 250 mg/day on days 2 to 5), clarithromycin (1 g/day in two divided doses for 7 days), erythromycin (2 g/day in four divided doses for 7 days), or trimethoprim/sulfamethoxazole (trimethoprim 320 mg/day, sulfamethoxazole 1600 mg/day in two divided doses for 14 days). For parapertussis, *B. holmesii*, and *B. bronchiseptica*, treatment is as for pertussis. Resistance to macrolide antibiotics is extremely common in some parts of China but not currently in other locales.[17]

PREVENTION

Immunization

Killed, whole-cell pertussis vaccines, which became widely used in the United States, reduced reported cases of pertussis from more than 200,000 annually to less than 2000 in 1980. However, concerns about side effects led to the switch to acellular pertussis vaccines, which cause significantly fewer adverse reactions but lose effectiveness after 2 to 3 years and have very limited ability to block person-to-person transmission of the pathogen.[A1]

In the United States, infants typically receive DTaP (diphtheria, tetanus, acellular pertussis), administered with inactivated polio vaccine and either hepatitis B vaccine or *Haemophilus influenzae* type B vaccine (Chapter 15). Booster vaccines (i.e., Tdap, where the capitalized T represents full-dose tetanus, and the lowercase "d" and "ap" refer to reduced-dose diphtheria and acellular pertussis, respectively) are recommended starting at age 11 years. Outside of the United States, whole-cell pertussis vaccines are similarly combined with other common injectable antigens in various combinations, including diphtheria, tetanus, and either *H. influenzae* type B or hepatitis B.

By 5 to 10 years after introduction of acellular pertussis vaccines, which elicit a shorter duration of immunologic protection compared with whole-cell vaccines, rates of clinical disease began to climb, reaching about 20,000 cases per year in the United States, though with significant year-to-year variation. Part of the problem may be a steady accumulation of *B. pertussis* strains that no longer express one or more of the virulence factors used as acellular vaccine antigens, presumably as an evolutionary response.

In addition, although both whole-cell and acellular pertussis vaccines are effective at preventing clinical illness, whole-cell vaccines abbreviate the duration of infection and reduce bacterial loads in the nasopharynx, whereas acellular vaccines have no impact on either the duration of colonization or the bacterial load. Consequently, recipients of acellular vaccine can infect others and perpetuate outbreaks, thereby undermining the strategy of vaccinating the household contacts of a newborn to prevent spread to the infant, a practice commonly referred to as "cocooning."

By contrast, maternal Tdap given later in pregnancy augments infants' passive IgG-mediated immunity to pertussis and is highly effective at reducing infant pertussis. Although such passive immunity is transient, it creates a bridge through the first 3 months of life, when infants are most vulnerable to severe pertussis and when pertussis deaths are concentrated. As a result, it is now recommended routinely in the United States for all pregnant women.

Candidate third-generation pertussis vaccines being tested in humans include a live-attenuated nasal vaccine designed to optimize local mucosal immune responses and a polysaccharide-protein conjugate vaccine linking *B. pertussis* capsule to pertussis toxin.[18] The emerging consensus is that the next generation of pertussis vaccines must block person-to-person spread by sterilizing mucosal immunity.

Chemoprophylaxis

Chemoprophylaxis with 5 days of azithromycin (500 mg on day 1, then 250 mg on days 2 to 5) is an important mechanism for controlling outbreaks in hospitals or the community. This approach is highly effective when initiated before the onset of symptoms but much less effective if started more than 14 days after the onset of symptoms in the index case.[19] Chemoprophylaxis is recommended for individuals exposed within the preceding 3 weeks, high-risk persons with underlying health problems, infants, other individuals who have not been immunized, and recently exposed individuals who have frequent occupational or other contact with susceptible hosts.

PROGNOSIS

Most patients will eventually clear *B. pertussis*, even without antimicrobial treatment, but 80% of adults with pertussis have an illness of at least 3 weeks' duration, and about 25% are still coughing after 90 days. Antimicrobial agents do not alter the course, and symptoms persist well beyond elimination of the causal organism. In contrast, infections with *B. bronchiseptica* are often long-lasting and require antibiotic treatment for clearance.

290 *LEGIONELLA* INFECTIONS

JONAS MARSCHALL AND VICTORIA J. FRASER

DEFINITION

Legionellosis refers to two clinical syndromes caused by *Legionella* bacteria: pneumonia and Pontiac fever. *Legionella* pneumonia (legionnaires disease) can be episodic or occur in outbreaks, and it can be acquired in the community or in health care settings. Pontiac fever is an acute, self-limited febrile illness caused by inhalation or aspiration of *Legionella* spp. *Legionella* extrapulmonary infections include meningitis, cellulitis, and skin and soft tissue abscesses. Endocarditis and wound infections also rarely occur.

The Pathogen

Legionellae are slender, noncapsulated, non-spore forming, obligatory aerobic, nutritionally fastidious, pleomorphic gram-negative bacilli (0.3-0.9 μm wide by 2-20 μm long) that belong to the Legionellaceae family (E-Fig. 290-1A to 1D). *Legionella* are facultative intracellular pathogens. *L. pneumophila* have a single polar flagellum. *L. longbeachae* differ in that they do not have a flagellum but have a capsule. *Legionella* spp. stain poorly on Gram stain. Warthin-Starry or Dieterle stains can demonstrate organisms in tissue. *L micdadei* and some other *Legionella* spp. may stain weakly acid-fast.

Legionella spp. have genomes that range in size from 2.37 to 4.88 Mb, but the core genome is comprised of only 1008 genes (6%). Recombination plays an important role in the organism's evolution and likely accounts for the development of new virulent strains as well as strains adapted to surviving in man-made water systems.[1]

EPIDEMIOLOGY

The Legionellaceae family has more than 60 species with more than 70 serogroups. *L. pneumophila*, which accounts for up to 90% of human infections, has more than 15 serogroups. Serogroup 1 is the most common cause of human infections, followed by serogroups 3, 4, and 6, although all groups can infect humans. *L. longbeachae*, which is more virulent than *L. pneumophila*, is the second most common species causing human disease, particularly in Australia and New Zealand. More than 25 *Legionella* spp. including: *L. micdadei, L. bozemanae, L. feeleii, L. anisa,* and *L. dumoffii* have been reported to cause human disease.

Legionella spp. are present in the environment worldwide. *L. pneumophila* and most *Legionella* spp. live in streams and lakes, and they thrive in man-made indoor and outdoor water systems, including drinking water, hot water pipes, fountains, air conditioning systems, and cooling towers. Almost all cases of legionnaires disease are due to exposure from *Legionella* contamination of man-made water sources.[2] *Legionella* can live either freely or as intracellular parasites in a number of different protozoans including *Acanthamoeba* and *Hartmannella* species (E-Fig. 290-1E). Growth of *Legionella* is promoted by warm temperatures, stagnation, and the presence of sediment in water systems. *Legionella* can withstand temperatures of 32 to 154° F (0 to 68° C), and they form biofilms that help them resist chlorination. The reservoir of *L. longbeachae* is in soil, including potting soil and compost, in contrast to other *Legionella*, which are more commonly found in water.

ABSTRACT

Legionellosis refers to both *Legionella* pneumonia (legionnaires disease) and Pontiac fever. *Legionella* pneumonia, which can be sporadic or epidemic, can be acquired in the community or health care setting. Pontiac fever is an acute, self-limited febrile illness caused by inhalation of *Legionella* spp. *Legionella* spp. are slender, noncapsulated, nonspore-forming, aerobic, nutritionally fastidious, gram-negative bacilli that belong to the Legionellaceae family. *L. pneumophila* serogroup 1 is the most commonly identified species that causes human disease. *Legionella* spp. are facultative intracellular pathogens found worldwide in water, both in the natural environment and in man-made water systems. Disease is caused by inhalation or microaspiration of water contaminated with *Legionella* spp. Waterborne outbreaks due to contaminated drinking water, air conditioning systems, water cooling towers, hot tubs, and other sources continue to occur, and reported rates of *Legionella* pneumonia are increasing. Signs and symptoms of *Legionella* pneumonia are similar to other causes of community-acquired pneumonia. A high index of suspicion is required to identify risk factors, perform specific laboratory testing, and establish the diagnosis. Early appropriate empiric antibiotic therapy improves outcomes.

Early *Legionella* outbreaks were difficult to solve and some persisted for months and even years. Since the eponymous outbreak at a Legionnaire's convention in Philadelphia in 1976, owing to a contaminated air conditioning system, numerous large, waterborne outbreaks around the world have involved drinking water, air conditioning systems, and water cooling towers in hospitals, in long term care facilities, in hotels, in apartment buildings, and on ships.

The incidence of *Legionella* infections varies geographically, related to the concentrations of *Legionella* in water systems as well as local heat and humidity. *L. pneumophila* infection is more common in the northeastern United States and Mediterranean regions.

Humans are accidental hosts for *Legionella*. Infection is typically acquired from inhalation or aspiration of *Legionella* contaminated water, including water used for drinking and bathing, air conditioning systems, hot tubs, birthing pools, decorative fountains, swimming pools, and water cooling towers. *Legionella* have surpassed gastrointestinal pathogens as the most common cause of waterborne outbreaks.

Legionella are commonly present in very low concentrations in cold, disinfectant-treated, potable water; however, bacterial density is amplified by growth in biofilms and replication in warm water and in older water systems with low or no flow. Significant changes in water pressure or water flow can disrupt biofilms, thereby releasing large numbers of organisms into the water. Contaminated water can be inhaled, aspirated, or ingested, thereby resulting in sporadic and epidemic infections. The exact dose required for infection is not known, but high numbers of organisms (>1000) are likely necessary.

L. pneumophila infections are more common in summer (E-Fig. 290-2), and most outbreaks occur between April and October. *L. longbeachae*, which is most commonly identified in soil and compost sources, usually causes disease in late spring and early summer in New Zealand and Australia, where it may account for 50% of *Legionella* cases.

Legionella can cause sporadic or epidemic, community-acquired pneumonia (Chapter 85) and health care–associated pneumonia (Chapters 85 and 261). Estimates of *Legionella* as a cause of community-acquired pneumonia requiring hospitalization range from 0.5 to 10% (average 2 to 5%). *Legionella* may account for up to 30% of nosocomial pneumonia. The reported incidence of legionnaires disease in the United States increased almost five- to six-fold from 1992 to 2018[3] (to approximately 2.29/100,000 persons), likely due to increased numbers of immunosuppressed individuals, the increased age of the population, increased testing, and greater awareness. Most U.S. cases are in the northeast, mid-Atlantic, and central regions. Of the 7500 annual cases, about 80% are in persons over age 50 years, about 60% of cases are in men, and the incidence rate is about 80% higher among Blacks compared with Whites.[4]

However, legionnaires disease is likely underdiagnosed and under-reported, and an estimated 18,000 to 88,000 total cases may occur per year in the United States. Most cases are sporadic and occur in outpatients, whereas outbreaks account for only 5 to 10% of legionnaires cases in the United States.

Activities that increase the risk of exposure to *L. pneumophila* spp. include overnight travel, recent plumbing work, disruptions of water supplies, older plumbing, use of whirlpools, hot springs, and proximity to cooling towers and decorative fountains. Travel–associated outbreaks are generally caused by contaminated potable water and cooling towers in hotels and contaminated hot tubs in ship–related outbreaks.[5] Risk factors for infection with *L. longbeachae* include working with compost or potting soil, smoking, chronic obstructive lung disease, and lack of handwashing after working with soil. Risk factors for developing symptomatic legionnaires disease include male gender, smoking, advanced age, dialysis-dependent renal failure, chronic lung or cardiovascular disease, diabetes mellitus, hematologic malignancies, and immunosuppression, particularly decreased cell mediated immunity, and the use of biologic immunosuppressive agents.

Nosocomial infections occur when contaminated water is inhaled, aspirated, or inoculated into the respiratory tract, most commonly from use of contaminated tap water used in nebulizers, humidifiers, and nasogastric feeding.[6] Health care–associated outbreaks typically account for more than half of the epidemics and more than 85% of the deaths due to *Legionella*.[7,8]

Pontiac fever has very high attack rates and more commonly occurs in outbreaks, in which 80 to 90% of exposed individuals become sick. Pontiac fever has been reported with *L. pneumophila*, *L. micdadei*, *L. anisa*, and other *Legionella* spp. High levels of *Legionella* contamination of potable water, showerheads, and cooling towers have been associated with outbreaks of Pontiac fever.

PATHOBIOLOGY

Free-living *Legionella* can enter low metabolic states and remain viable but not cultivable, so they are both resistant to biocides and difficult to recover from the environment. They also form biofilms, which aid in their resistance to biocides and chlorination. The ability to grow in temperatures from 68 to 107.6° F (20 to 42° C) and tolerate pH ranges from 5 to 8.5 contributes to their resilience. *Legionella* cannot be cultured on ordinary media; buffered charcoal yeast extract agar is required to cultivate *Legionella*, which grow best at 35° C in humidified air. Colonies are generally visible at 3 to 5 days, but incubation up to 14 days may be necessary to identify unusual species. Given the difficulties growing *Legionella* in the laboratory, negative culture results do not exclude the diagnosis.

After inhalation or microaspiration of *Legionella* contaminated water, droplet nuclei, which are less than 5 μm in size, reach the alveoli. In the alveoli, bacteria attach to macrophages and epithelial cells using outer membrane porins, flagella, and pili. Human complement component C3 mediates phagocytosis in conjunction with a virulence factor, macrophage infectivity potentiator protein, which is expressed on the cell surface of *L. pneumophila*.[9] Once phagocytized, *L. pneumophila* translocates hundreds of effector proteins into a specialized compartment, termed the *Legionella*-containing vacuole, through a Dot/Icm (delayed in organ trafficking/intracellular multiplication) type IV secretion system. Phagosome-lysosome fusion is inhibited by the effector proteins, which allow *L. pneumophila* to survive intracellularly in the *Legionella* containing vacuole. The vacuole is transformed into an organelle through recruitment of vesicles from the host's endoplasmic reticulum. Intracellular bacterial replication causes the vacuole to expand, ultimately filling the cell. When the host cell's nutrients are exhausted, the bacteria transition to a stationary growth phase and develop flagella. Caspase-1, which is triggered by the flagella, induces apoptosis and releases bacteria from the cell.

Legionella are able to resist complement and cationic peptides in the extracellular space, thereby avoiding free radicals. Bacteria in the extracellular space reenter more cells and trigger additional replication cycles, thereby amplifying the concentration of bacteria in the lung. *Legionella* uses a type II secretion system to secrete degradative enzymes and toxins. Infected macrophages release chemokines and cytokines that trigger a severe inflammatory response. A progressive, destructive pneumonia is caused by chemotactic substances, which attract polymorphonuclear leukocytes and monocytes, as well as the subsequent inflammatory response.

The predominant mechanism of immune control of *Legionella* is through Th1 cell mediated immunity. Infected alveolar macrophages incite the recruitment of neutrophils and stimulate natural killer cells to produce interferon gamma, which is key to eradicating *Legionella* from the lung. Innate immunity against *Legionella* involves toll-like receptors (TLR) 2, TLR 4, TLR5 and TLR89. Formation of inflammasomes leads to proteolytic activation of caspase-1. Cleavage of pro-interleukin – β (IL-Iβ) and release of IL-1β leads to an inflammatory form of cell death called pyroptosis. Pyroptosis is thought to be the main mechanism by which host cells control the growth of *L. pneumophila*. Individuals with TLR5 stop codon polymorphisms are more susceptible to legionnaires disease, whereas TLR4 polymorphisms are protective.[10]

Pontiac fever is caused by inhaling *Legionella* contaminated aerosols. The aerosols often contain *Legionella*, endotoxins, and other microorganisms, so it is not clear if the disease is due to the *Legionella* bacteria alone, a polymicrobial aerosol, or endotoxins from *Legionella* or other organisms. The short incubation period of 4 to 6 hours in some patients supports a toxin-mediated illness, whereas the longer incubation of 35 hours in some patients suggests bacterial illness.

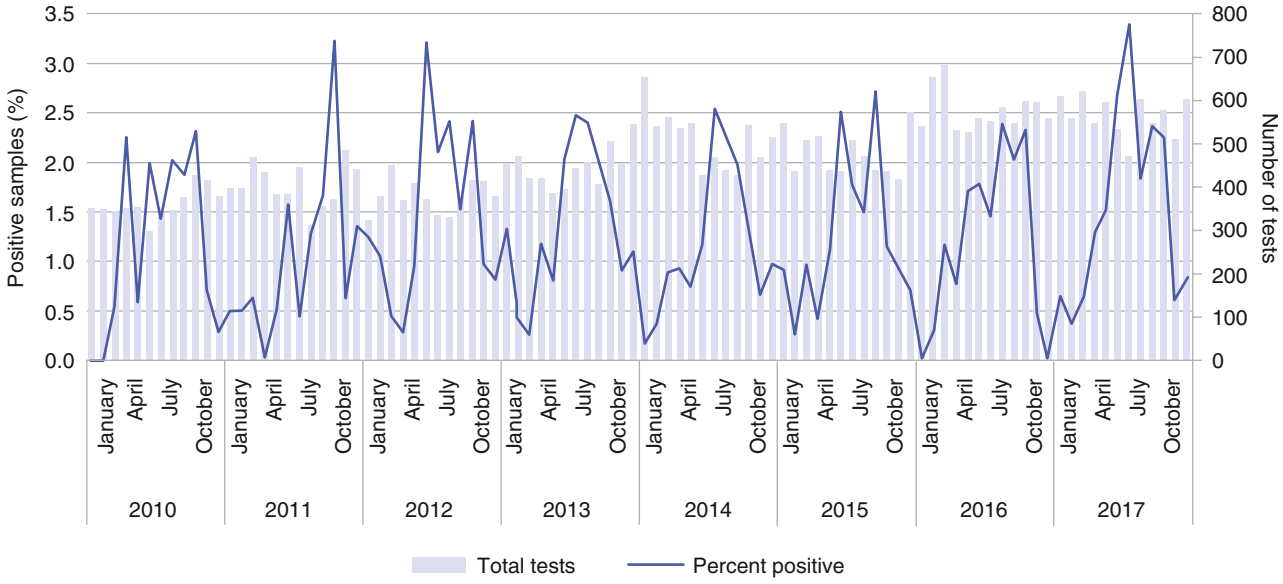
Very little is known about the pathogenesis, virulence, and cell biology of infections caused by *Legionella* spp. other than *L. pneumophila*. However, different species have different virulence factors and effector proteins. *L. longbeachae* lacks flagella and has a larger genome than *L. pneumophila*. These additional genetic sequences may increase *L. longbeachae's* pathogenicity.

Gross pathology from post-mortem examination of patients who died from legionnaires disease demonstrates patchy or focal lesions in a third of cases, focal hemorrhage in one quarter of patients, and lobar pneumonia in 50% of patients. Microscopic examination demonstrates diffuse alveolar damage, bronchopneumonia and dense congestion with macrophages, neutrophils, and inflammatory debris (E-Fig. 290-3A to 3D). Blood vessel inflammation suggesting vasculitis may occasionally be present.

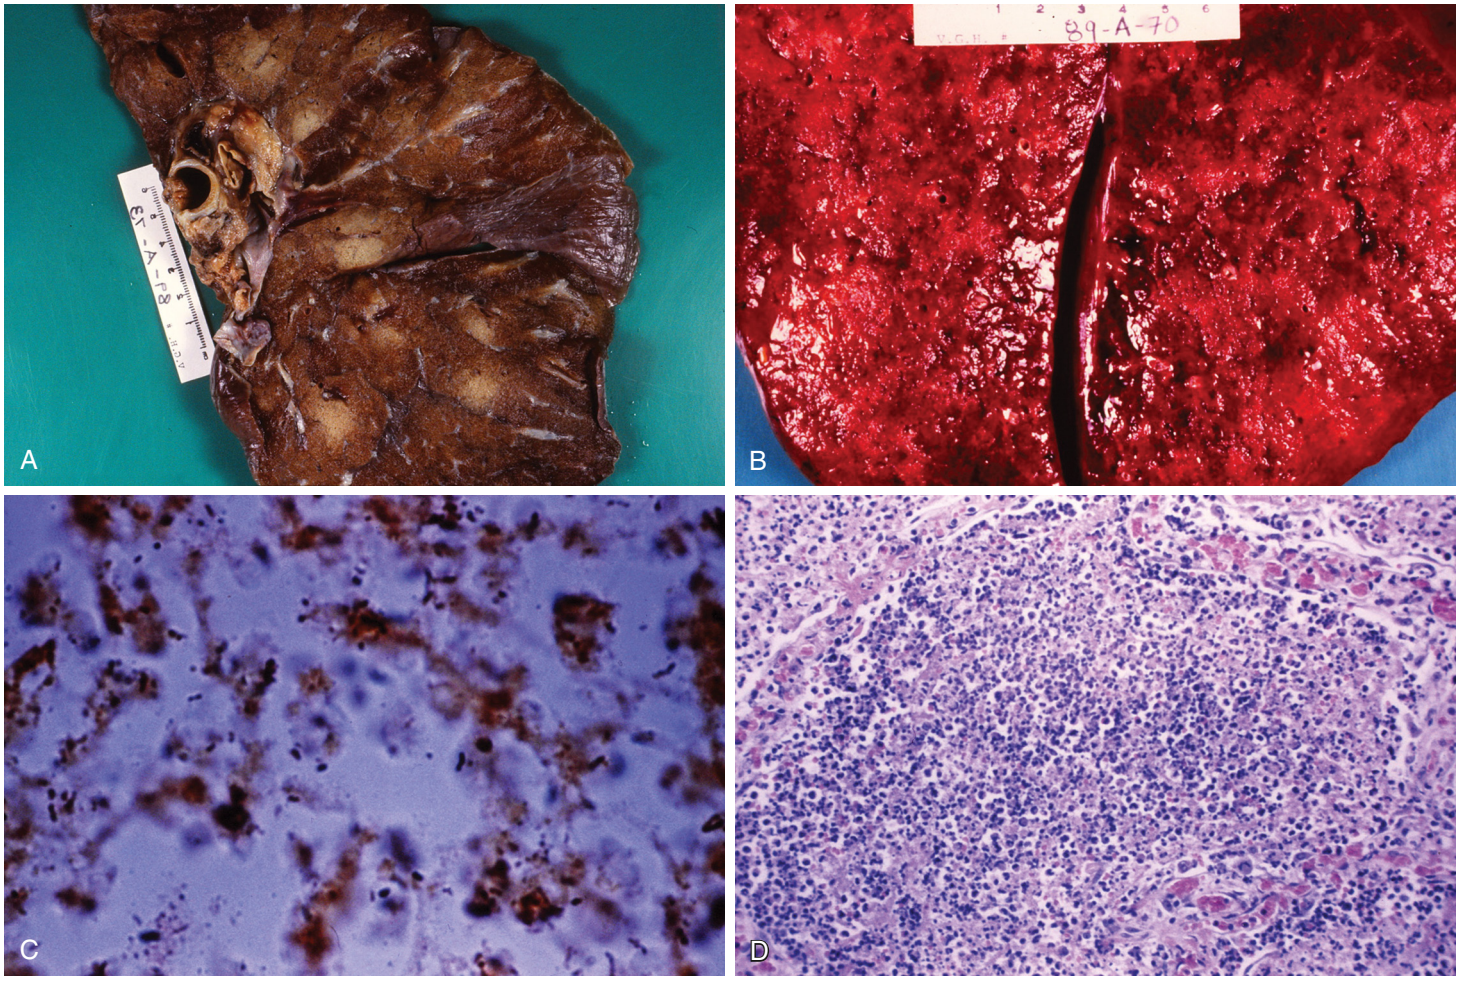
CLINICAL MANIFESTATIONS

Pneumonia

After an incubation of usually 2 to 10 days but occasionally as long as 28 days after exposure, patients with legionnaires disease often present with a nonspecific prodrome that persists for hours to days with anorexia, asthenia, headache, myalgia, and fever. Rigors, nausea, vomiting, diarrhea, and abdominal pain may precede pulmonary symptoms. Neurologic symptoms including headache and confusion are common. The prodromal phase often results in delayed diagnosis because the systemic symptoms do not relate to the lower respiratory track.



E-FIGURE 290-2. **Seasonality of *Legionella* detection by real-time polymerase chain reaction (PCR).** Data were obtained with PCR testing of more than 44,000 *Legionella* PCR tests on Mayo Clinic and Mayo Laboratories patients between January 2010 and December 2017. Average monthly *Legionella* PCR-positivity rates and test volumes over 8 years (2010–2017). The *dark-blue line* represents the mean monthly positivity, and the *light-blue bars* represent average monthly test volumes. (From Rucinski SL, Murphy MP, Kies KD, et al. Eight years of clinical *Legionella* PCR testing illustrate seasonal pattern. *J Infect Dis*. 2018;218:669-670.)



E-FIGURE 290-3. **Pathology in fatal legionnaires disease.** **A**, Gross pathology specimen of formalin-fixed lung from a patient with nosocomial legionnaires disease. Note the multiple nodular consolidated areas. **B**, Gross appearance of fresh lung tissue from a patient with legionnaires disease. Note the "hepatization of the lung" representing consolidation. **C**, Dieterle stain on lung tissue from a patient with legionnaires disease showing many microorganisms (magnification ×1000). **D**, Histologic appearance of pulmonary tissue from a patient with legionnaires disease. Note the dense inflammatory infiltrate with evolving microabscesses (magnification ×200).

Patients with pneumonia typically seek medical care at an average of 4.7 days after the onset of symptoms.[11] The clinical manifestations of *Legionella* pneumonia are similar to pneumococcal pneumonia and other causes of bacterial and atypical community acquired pneumonia (Chapter 85). Typical symptoms include high fever (of 40.5° C in up to a third of patients), rigors, cough, and shortness of breath. The cough is typically nonproductive, but some patients have thin watery sputum or purulent sputum, occasionally with blood streaking. Pleuritic or nonpleuritic chest pain may be reported. Acutely ill patients can develop rhabdomyolysis and acute kidney injury. *L. longbeachae*, which is the second most common cause of legionnaires disease, has clinical manifestations similar to that of *L. pneumophila*.

The initial lung examination may demonstrate only a few crackles before full-blown consolidation is evident. Abdominal tenderness, organomegaly, nuchal rigidity, and focal neurologic deficits have been reported.

Nonspecific laboratory abnormalities include hyponatremia (in 50% of patients, sometimes severe), hypophosphatemia, and elevated levels of serum creatinine, aminotransferases, bilirubin, and creatine kinase. Myoglobinuria and proteinuria can be associated with rhabdomyolysis. Leukopenia and thrombocytopenia may be present in severely ill patients. Cold agglutinins may be present. A serum procalcitonin level greater than 1.5 ng/mL is seen more commonly in *Legionella* patients admitted to intensive care units.

Chest radiographic findings in legionnaires disease are similar to other community-acquired pneumonias (Chapters 72 and 85). Unilobular or multilobular consolidated opacities in the middle or lower lobes are common (Fig. 290-1), and up to one third of patients have pleural effusions. Interstitial and nodular infiltrates can develop. Lung abscesses and cavitation are uncommon but can occur, particularly in immunosuppressed patients. Chest computed tomographic (CT) scanning is more sensitive than chest radiography and should be considered in patients who fail to respond to appropriate antibiotic therapy to evaluate for pulmonary complications.

Pontiac Fever

Within 4 to 6 hours after exposure, fatigue, malaise, and myalgias occur in more than 90% of patients with Pontiac fever. Fever and chills develop in 80 to 90% of patients, and headache in 80%. Cough, anorexia, arthralgia, nausea, vomiting, and abdominal pain each occur in less than 50% of patients. Mild to moderate leukocytosis may be present. Pneumonia does not occur.

Extrapulmonary Infections

Extrapulmonary *Legionella* infections are rare and generally are a result of bacteremic seeding in the setting of pneumonia or as direct complications of pneumonia. However, a wide variety of extrapulmonary infections can occur in immunosuppressed hosts, including septic arthritis, prosthetic joint infections, native and prosthetic valve endocarditis, intraabdominal abscesses, surgical wound infections, myocarditis, pericarditis, osteomyelitis, skin and soft tissue infections, and meningitis. Extrapulmonary infections are more likely to be caused by *Legionella* spp. other than *L. pneumophila*.

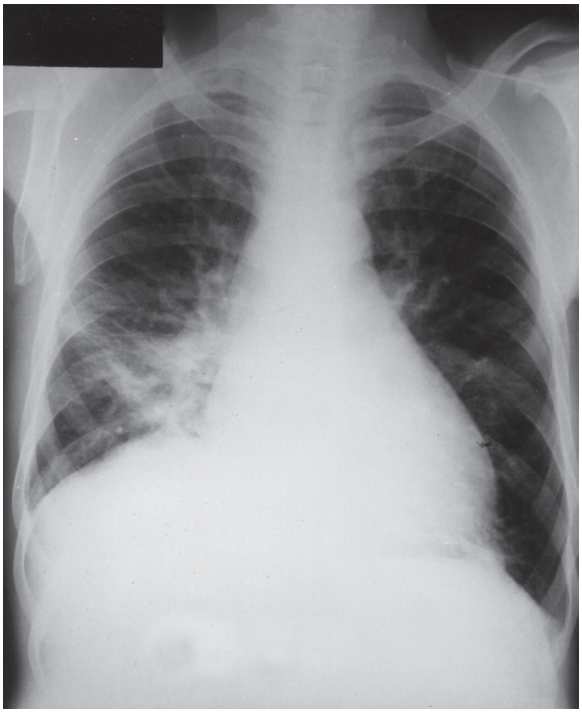


FIGURE 290-1. Posteroanterior chest radiograph of a patient with community-acquired pneumonia due to *Legionella pneumophila*. There is patchy consolidation at the right base, with subsegmental atelectasis and elevation of the right hemidiaphragm.

DIAGNOSIS

Legionnaires disease should be suspected in patients with rapidly progressive and/or moderate to severe pneumonia. No particular signs or symptoms reliably differentiate legionnaires disease from other pneumonias, but gastrointestinal symptoms (e.g., diarrhea, nausea, vomiting, elevated liver enzymes) and failure to respond to β-lactam monotherapy should raise suspicion for *Legionella* infection.[12]

In routine clinical care, symptoms and signs rarely differentiate among the various causes of community acquired pneumonia (Chapter 85), and treatment with a macrolide or fluoroquinolone antibiotic commonly obviates the need for the specific identification of *Legionella* spp. However, diagnostic testing for legionnaires disease should be performed in patients with severe community–acquired pneumonia, pneumonia that is unresponsive to outpatient therapy, immunosuppressed patients, patients with risk factors or water exposures, hospitalized patients, patients who progress on monotherapy with β-lactam antibiotics, and during outbreaks.

Polymerase chain reaction (PCR) testing can be performed on sputum, bronchial alveolar lavage specimens, tracheal aspirates, pleural fluid, or other tissues and fluids. Lower respiratory specimens are preferred for diagnosis. Real-time PCR rapidly detects all *Legionella* spp. and serogroups with high diagnostic accuracy (sensitivity 95 to 99% and specificity > 99%).[13] Genus specific PCR tests to detect all known *Legionella* spp. are helpful in immunosuppressed patients and patients who may not have *L. pneumophila*. Genetic sequencing of positive PCR samples or whole genome sequencing can be used for molecular epidemiology and species level identification.

Urinary antigen testing is readily available, inexpensive, and rapid, but it detects only *L. pneumophila* serogroup 1 with a sensitivity that ranges from 70 to 80% and specificity that approaches 100%.[14] Antigen can be detected within a day of the onset of symptoms and 1 to 2 weeks afterward.

A positive culture for *Legionella* is considered the gold standard. Culture can be performed on sputum, bronchoalveolar lavage specimens, tracheal aspirates, or pleural fluid. Sputum samples may be difficult to obtain in patients with *Legionella* pneumonia; the sensitivity of sputum culture ranges widely from less than 10% to 70 to 80%, and prior antimicrobial therapy decreases the likelihood of positive culture results. Tracheal aspirates and bronchoscopically obtained deep respiratory samples have higher yields and should be performed in patients with severe disease, immunosuppressed patients, patients who are progressing on therapy, and patients with risk factors for *Legionella*. Culture, which can detect all *Legionella* spp., provides bacterial isolates for susceptibility testing, and its isolates can be sequenced to investigate outbreaks.

The diagnosis of extrapulmonary infections is made by culture or performing PCR on tissues or fluid from the infected site. The value of blood cultures is limited. However, up to 10% of critically ill and immunocompromised patients may be bacteremic.

The most commonly used serologic tests are indirect fluorescent antibody tests or ELISA tests. A four-fold rise in antibody titers, ideally at 4, 6, and 12 weeks, is diagnostic and useful for retrospective confirmation and for the evaluation of outbreaks. Pontiac fever, which is often identified in outbreaks with high attack rates of 70 to 90%, is diagnosed by a fourfold rise in serology.

Differential Diagnosis

The differential diagnosis of *Legionella* pneumonia includes common causes of community–acquired pneumonia (Chapter 85), including *Streptococcus pneumoniae* (Chapter 268), *Haemophilus influenzae* (Chapter 277), Mycoplasma (Chapter 293), and viral pneumonias. For health care–associated pneumonias (Chapters 85 and 261), the differential diagnosis includes *Staphylococcus aureus* (Chapter 267), *Pseudomonas* (Chapter 282), and other gram-negative bacterial pneumonias (Chapters 282 and 283).

TREATMENT

Community-Acquired Pneumonia

Early empiric therapy of community-acquired pneumonia (Chapter 85) is associated with improved outcomes for patients with *Legionella* infections. The recommended treatment is levofloxacin (750 mg orally or intravenously once daily for 5 to 10 days) or azithromycin (500 mg orally or intravenously daily for a total of 3 to 7 days; Table 290-1),[A1,A2] Levofloxacin (750 mg orally or intravenously once daily for

TABLE 290-1 TREATMENT FOR LEGIONNAIRES DISEASE

SEVERITY OF *LEGIONELLA* PNEUMONIA	PREFERRED REGIMENS	ALTERNATIVE REGIMENS
Mild pneumonia (CURB-65 [see Table 85-4] score of 0 or Pneumonia Severity Index [see Fig. 85-3 and Table 85-3] class I-II) It is not necessary to change from alternate to preferred therapy if patients are responding to alternate therapy.	Azithromycin 500 mg orally once daily Levofloxacin 750 mg orally once daily	Ciprofloxacin* 500 mg orally twice daily Moxifloxacin 400 mg orally once daily Clarithromycin* 500 mg orally twice daily Doxycycline 200 mg orally once followed by 100 mg orally twice daily (should not be used for *L. longbeachae* as this organism is resistant to tetracyclines)
Moderate to severe pneumonia (hospitalized patients or patients with CURB-65 score ≥1 or Pneumonia Severity Index ≥II) IV therapy is recommended initially for hospitalized patients and those with moderate-severe pneumonia. IV therapy can be converted to oral when patients are hemodynamically stable, able to tolerate oral therapy and clinically improving.	Azithromycin 500 mg IV or orally once daily Levofloxacin 750 mg IV or orally once daily	Ciprofloxacin* 400 mg IV twice daily or 750 mg orally twice daily Moxifloxacin 400 mg IV or orally once daily Clarithromycin* 500 mg IV or orally twice daily (IV formulation not available in the United States)

*Ciprofloxacin and clarithromycin need dose adjustment for renal dysfunction.

Duration of therapy is determined based on the patient's severity of illness, presence of comorbid conditions, immunosuppression, and infectious complications. In general, short course therapy with minimum duration of 5 days of therapy is possible for patients with mild pneumonia who have been clinically stable and afebrile for 48 hours. Mild pneumonia is generally treated with 5 to 7 days of therapy. Patients with severe infection or multiple chronic comorbidities usually require 7 to 10 days of therapy. Longer duration of therapy (up to 21 days or longer) may be required for immunosuppressed patients and patients who have extrapulmonary infections, lung abscess, or empyema.

IV = intravenous.

5 to 10 days) is recommended for extrapulmonary infections. Intravenous therapy is preferred for patients with moderate-severe disease and should be transitioned to oral therapy when the patient is improving and able to tolerate oral medications. Alternatives include moxifloxacin (400 mg orally or intravenously once daily for 7 to 10 days) or doxycycline (200 mg orally as a loading dose followed by 100 mg orally twice daily for 10 to 14 days). Dual therapy is not recommended for *Legionella* unless a coinfection or superinfection is suspected. None of the β-lactam, monobactam, aminoglycoside or phenicol antibiotics are active against *Legionella*. In outbreak settings, moderate to severe pneumonia, patients with multiple comorbid conditions, immunosuppressed patients, and high prevalence areas, empiric therapy with a fluoroquinolone or macrolide antibiotic to cover *Legionella* should be started early while awaiting results of diagnostic testing.

The optimal duration of therapy is not well defined. Short course (minimum of 5 days) therapy can be used in otherwise healthy patients who have mild disease, are clinically improving, are hemodynamically stable, and are afebrile for 48 hours. Longer duration (7 to 10 days) of therapy is recommended for severe disease and in elderly patients who have multiple comorbid conditions. Immunosuppressed patients and transplant recipients should receive at least 14 days of therapy. Patients with extrapulmonary infections, lung abscess, or empyema generally require longer therapy and possibly debridement, drainage, or surgical interventions based on the nature of the infection and complication.

L. longbeachae, which is more common in Australia and New Zealand, is often resistant to doxycycline and other tetracyclines, which should not be used to treat it. In these areas, fluoroquinolone or macrolide therapy is the preferred empiric regimen.[15]

Correction of fluid and electrolyte abnormalities and of hypoxemia (Chapter 90) is important. The indications for adjunctive therapy, including minimizing immunosuppression or using glucocorticoids to control inflammation, are similar as for other community-acquired pneumonias (Chapter 85). Mechanical ventilation (Chapter 91) and extracorporeal membrane oxygenation can improve survival in patients with potentially reversible, severe respiratory failure.

Some patients, particularly elderly patients with multiple comorbid conditions, continue to worsen despite appropriate therapy. Failure to respond to specific therapy should prompt investigation of alternative diagnoses or the possibility of coinfections or superinfections, which complicate about 10% of patients with legionnaires disease.[16]

PREVENTION

Legionella is not transmitted person to person, so patients do not require isolation. No vaccine is available. Prior infection does not prevent reinfection. Antibiotic prophylaxis with the same drugs, doses, and durations used for treatment can also be used to prevent legionnaires disease in exposed immunosuppressed hosts during outbreaks.

A single case of *Legionella* should prompt communication with the microbiology laboratory and public health officials to assess for a common source and outbreak. Health care–associated legionellosis should prompt extensive investigations to identify the source of contamination. Retrospective review of microbiology results may identify additional cases that were presumed to be sporadic. Prospective laboratory testing for *Legionella* in patients with nosocomial and community-acquired pneumonia may be indicated to define the extent of an outbreak. Epidemiologic investigations, environmental cultures, and molecular analysis are necessary components in investigations of a potential outbreak and can guide interventions to eliminate the source of contamination.

Prevention of legionellosis depends upon identifying the environmental source and decreasing colonization of potable water to prevent further exposures. Water systems should be designed to reduce the risk of heavy *Legionella* colonization by avoiding dead spaces, stagnation, and materials that allow accumulation of sediment. Surveillance and monitoring for *Legionella* spp. is recommended for water systems in high-risk areas, such as hospitals and long-term care facilities.

Water disinfection is common in developed countries and includes use of point source filters, copper-silver ionization, heat shock, chlorine dioxide, and monochloramine. Use of monochloramine to treat drinking water decreases colonization with *Legionella* spp. and nosocomial legionnaires disease. Long-term control and prevention of *Legionella* overgrowth in water systems is complicated and requires expert public health and engineering input.[17-19] In areas where *L. longbeachae* is prevalent, gardeners and persons working with soil or compost should be advised to use good handwashing, avoid contaminating their face with dirt, and minimize aerosolizing compost and soil, especially if they are immunocompromised.

PROGNOSIS

Early diagnosis and appropriate treatment are associated with improved outcomes.[20] Most patients respond quickly to appropriate therapy, with improvement or resolution of myalgias, headache, abdominal pain, diarrhea, nausea, vomiting, anorexia, and confusion within 12 to 24 hours. Cough, sputum production, and shortness of breath usually respond more slowly. Patients generally become afebrile in 2 to 5 days. Radiographic changes are slower to resolve and may take up to 2 months or longer to return to baseline. Convalescence and complete recovery may take months, especially in immunosuppressed and elderly patients.

The reported mortality for legionnaires disease ranges from 1 to 80%, but the average mortality for sporadic hospitalized cases is estimated to be 10 to 15%. Mortality is higher in patients who are elderly, immunosuppressed, or have multiple comorbid conditions. The mortality is also higher when effective therapy is not begun promptly. Oliguria and acute renal failure may occur and dialysis may be required in severely ill patients.

Pontiac Fever

Pontiac fever is generally acute and self-limited and it usually resolves over 1 to 9 days without specific therapy. However, fatigue and nonspecific complaints may persist for months in some patients.

291 *BARTONELLA* INFECTIONS

JEAN-MARC ROLAIN AND DIDIER RAOULT

DEFINITION

Bartonella are vector-borne bacteria responsible for a wide spectrum of human acute and chronic diseases. More than 40 different bacterial species from this genus have been isolated from animals and humans. The human infections linked to these different bacteria include cat-scratch disease, Oroya fever, verruga peruana, trench fever, endocarditis, bacillary angiomatosis, and peliosis hepatis.

The Pathogen

Bartonella species belong to the α-2 subgroup of Proteobacteria and are closely related to the genera *Brucella*, *Agrobacterium*, and *Rhizobium*. *Bartonella* species are small, gram-negative, fastidious, pleomorphic coccobacilli or slightly curved rods (0.5 by 1 to 2 μm). The bacteria can grow on enriched blood-containing media with a 5% carbon dioxide atmosphere after 5 to 15 days to up to 45 days on primary culture. The optimal growth temperature ranges from 28° C for *B. bacilliformis* to 35° to 37° C for the other species. *Bartonella* species can also be cocultured with endothelial cells. *Bartonella* species are either flagellated or nonflagellated cells. *B. bacilliformis* uses flagella for binding and deforming into the surface of erythrocytes. Bacteria can either persist in the blood stream of the host as intraerythrocytic parasites or colonize human endothelial cells.

EPIDEMIOLOGY

More than 40 known *Bartonella* species have been isolated from both animals and humans. These bacteria are zoonotic, and the strains that are associated with human infections include *B. henselae, B. quintana, B. bacilliformis, B. elizabethae, B. clarridgeiae, B. vinsonii* subsp. *arupensis, B. vinsonii* subsp. *berkhoffii, B. alsatica, B. tamiae, B. grahamii, B. washoensis, B. rochalimae, B. koehlerae, B. mayotimonensis*, and *B. ancashensis* (Table 291-1). The other *Bartonella* species have been isolated only from the blood of animals, including rodents, felids, canids, dolphins, bats, and ruminants. The route of transmission of *Bartonella* species in mammals and humans is by fleas, ticks, mites, and lice (see Table 291-1).

TABLE 291-1 *BARTONELLA* SPECIES CAUSING HUMAN DISEASE

BARTONELLA SPECIES	RESERVOIR HOST/ VECTOR	HUMAN DISEASE
B. alsatica	Rabbit	Endocarditis, lymphadenopathy
B. ancashensis		Verruga peruana
B. bacilliformis	Human/sandfly	Carrión disease, Oroya fever, verruga peruana
B. clarridgeiae	Cat/cat flea	Cat-scratch disease
B. elizabethae	Rat	Endocarditis, neuroretinitis
B. grahamii	Rat, insectivore	Neuroretinitis
B. henselae	Cat/cat flea	Cat-scratch disease, endocarditis, bacillary angiomatosis, bacillary peliosis, Parinaud oculoglandular syndrome, neuroretinitis, osteomyelitis, arthropathy, bacteremia with fever
B. koehlerae	Cat	Endocarditis
B. mayotimonensis	Unknown	Endocarditis
B. quintana	Human/body louse	Trench fever, endocarditis, bacillary angiomatosis
B. rochalimae		Bacteremia, fever, splenomegaly
B. tamiae		Febrile illness
B. vinsonii arupensis	Dog, rodent/ticks	Bacteremia with fever
B. vinsonii berkhoffii	Dog	Endocarditis
B. washoensis	Ground squirrel	Myocarditis

Almost all *Bartonella* species are vector-borne bacteria (see Table 291-1). Some are limited geographically, such as *B. bacilliformis*, which is found only in the Andes Mountains in South America at high altitudes, where its principal vector, *Lutzomyia verrucarum*, is distributed. Others have a worldwide distribution, such as *B. henselae* and *B. quintana*. Each *Bartonella* species is highly adapted to its mammalian reservoir, in which bacteria usually cause a long-lasting intraerythrocytic bacteremia that may be asymptomatic. Humans are the hosts and reservoirs for *B. bacilliformis* and *B. quintana*. *B. quintana*, which is transmitted by the human body louse by inoculation of arthropod feces through broken skin, is more common in homeless persons[1] and in poorer countries.[2] Cats represent the main reservoir hosts for *B. henselae* infection; this pathogen is the agent of cat-scratch disease in humans, caused by cat bites or scratches. In the United States, about 12,000 outpatients and 500 inpatients are diagnosed annually.[3] *B. henselae* infection is transmitted from cat to cat by the cat flea. Cat fleas may also be infected by *B. quintana*. The role of dogs as reservoir hosts has been documented for several species, including *B. vinsonii* subsp. *arupensis*, *B. vinsonii* subsp. *berkhoffii*, and *B. henselae*. Wild rabbits are the reservoir hosts for *B. alsatica*, which is an agent of endocarditis and lymphadenopathy in humans in close contact with rabbits. For other *Bartonella* species known to cause diseases in humans, the pathogenic role and mode of transmission are not fully understood.

PATHOBIOLOGY

A single *Bartonella* species can cause either acute or chronic infections and either vasculoproliferative or suppurative manifestations but with different pathogenetic mechanisms that mainly depend on the patient's immune status. For example, *B. henselae* usually causes cat-scratch disease (a self-limited disease) in immunocompetent hosts, whereas it is responsible for bacillary angiomatosis in immunocompromised patients. *B. quintana* is responsible for trench fever as well as for endocarditis, bacteremia in the homeless population, and vasculoproliferative diseases, whereas *B. bacilliformis* is the agent of Carrión disease, which corresponds to either an acute intraerythrocytic bacteremic disease (Oroya fever) or a chronic vasculoproliferative disease (verruga peruana). *B. bacilliformis* (Oroya fever) and *B. quintana* (trench fever and bacteremia in the homeless) infect red blood cells, whereas *B. henselae* and *B. koehlerae* have been seen in erythrocytes of infected cats. *B. henselae* can cause granulomatous disease (i.e., cat-scratch disease), which affects lymph nodes, but it can also be responsible for other clinical manifestations or complications, such as endocarditis. Vasculoproliferative diseases include bacillary angiomatosis caused by *B. henselae* and *B. quintana*, peliosis hepatis caused by *B. henselae*, and verruga peruana caused by *B. bacilliformis*. In patients with a previous valvulopathy, any *Bartonella* infection may lead to endocarditis.

CLINICAL MANIFESTATIONS

Bartonella infections can lead to a wide spectrum of either acute or chronic diseases. The status of the host immune response plays an important role in the development of the different manifestations. Four different groups of clinical syndromes may occur with *Bartonella* infections: (1) infection of red blood cells and erythrophagocytosis, (2) granulomatous disease controlled by the immune response, (3) bacteremia and blood culture–negative endocarditis, and (4) vasculoproliferative diseases (bacillary angiomatosis, peliosis hepatis, and verruga peruana) (Table 291-2). In a recent French study, 89% of *Bartonella* infections were cat-scratch fever, 9% were endocarditis, and 2% were bacillary angiomatoses or peliosis hepatis.[4]

INTRAERYTHROCYTIC BACTEREMIA: OROYA FEVER AND TRENCH FEVER

EPIDEMIOLOGY AND PATHOBIOLOGY

The vector of *B. bacilliformis* is the mosquito *Lutzomyia verrucarum*, whereas *B. quintana* is transmitted via human body louse. In Oroya fever, *B. bacilliformis* invades up to 80% of erythrocytes and produces their massive lysis, which results in severe hemolytic anemia, the major symptom of the disease. Similarly, trench fever is characterized by intracellular erythrocyte parasitism by *B. quintana*, with the percentage of infected red blood cells ranging from 0.001 to 0.005% (Fig. 291-1). Bacteria can also be seen extracellularly and in erythroblasts. This intracellular erythrocyte parasitism can presumably preserve the pathogens for efficient transmission by body lice, protect *B. quintana* from the host immune response, and contribute to decreased antimicrobial efficacy. During bacteremia in the homeless, *B. quintana* can also be seen in red blood cells.

CLINICAL MANIFESTATIONS

Oroya Fever

Oroya fever is the acute or hemolytic phase of Carrión disease,[5] which is also associated with a chronic phase called verruga peruana (see later). Oroya fever

ABSTRACT

Bartonella are vector-borne bacteria responsible for a wide spectrum of human acute and chronic diseases. More than 40 different bacterial species from this genus have been isolated from animals and humans. The human infections linked to these different bacteria include cat-scratch disease, Oroya fever, verruga peruana, trench fever, endocarditis, bacillary angiomatosis, and peliosis hepatis.

*The combination of intraerythrocytic bacteremia and verruga peruana is also known as Carrión disease.
CSD = cat-scratch disease; SENLAT = scalp eschar and neck lymphadenopathy.

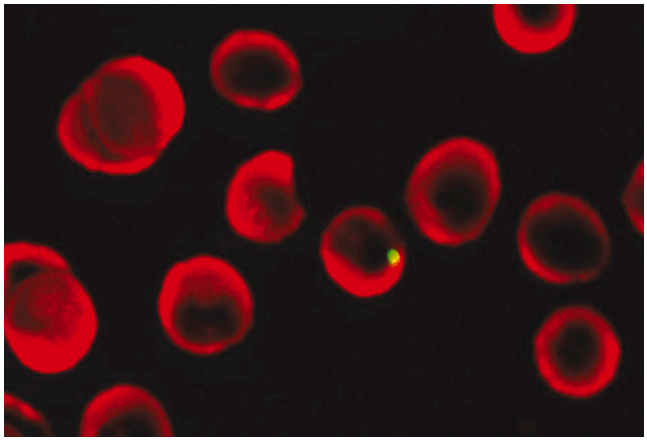

FIGURE 291-1. Section of human red blood cell infected with *Bartonella quintana* as viewed by confocal microscopy.

usually develops 3 to 12 weeks after inoculation with *B. bacilliformis* and results from the massive invasion of erythrocytes. The onset is usually abrupt, with high fever, chills, headache, and anorexia. Patients have intense myalgias and arthralgias, abdominal pain, and jaundice. Complications are frequent, including meningoencephalitis, dyspnea, delirium, and superinfection leading to death. Asymptomatic persistent bacteremia may serve as the reservoir of the organism.

Trench Fever

Trench fever, which is transmitted by lice, is the clinical manifestation of *B. quintana*. Trench fever affected more than 1 million people during World War I; more recently, *B. quintana* has been recognized in immunocompromised hosts, homeless people, and people with chronic alcohol use disorder. Clinical manifestations of trench fever may range from asymptomatic infection to severe, life-threatening illness. After an incubation period of 2 to 3 weeks, sudden onset of fever persists for 1 to 3 days and is associated with headache, shin pain, and dizziness. The disease may persist for 4 to 6 weeks and result in prolonged disability. Relapses may occur years later in some cases with bacteremia but no clinical signs.

CAT-SCRATCH DISEASE

EPIDEMIOLOGY AND PATHOBIOLOGY

Transmission from cat to human occurs directly by a cat scratch or cat bite or possibly by a cat flea or tick bite. Little is known about the pathogenesis of the long-lasting lymphadenopathy in cat-scratch disease. Immunopathogenesis is assumed to play an important role in cat-scratch disease because bacteria have only rarely been isolated from affected lymph nodes. Thus, the disease is usually controlled by the host immune response, and few or no viable bacteria are seen on lymph node biopsy specimens, which are necrotic by pathologic examination.

CLINICAL MANIFESTATIONS

Typical cat-scratch disease, which is the most common manifestation of infection with *B. henselae*, usually is manifested as a self-limited regional lymphadenitis. A typical papule or pustule may be seen 3 to 10 days after the scratch or bite at the site of inoculation and may persist for 1 to 3 weeks. The subsequent lymphadenopathy is localized mainly to the axillary, cervical, or submaxillary nodes that drain the area where the cat scratch occurred. The enlarged lymph node is often painful and tender. Tick-borne *B. henselae* infection can present as a scalp eschar and neck lymphadenopathy.

Lymphadenopathy sometimes persists for months, and in a few cases it can persist for as long as 1 to 2 years. In some cases, the lymph node may suppurate if it is not drained. Most patients are not febrile during the course of typical cat-scratch disease. Systemic or severe disease may occur in about 5 to 14% of patients, owing to disseminated infection.

After exposure to *B. henselae*, patients may develop bacteremia with or without clinical signs of typical cat-scratch disease; in patients with preexisting valvular lesions, this bacteremia may result in infective endocarditis.[6] Since the organism is rarely grown on typical blood culture media, it is often a cause of fever of unknown origin[7] (Chapter 259) or "culture-negative endocarditis" (Chapter 61).[8]

Approximately 10% of patients with cat-scratch disease have atypical clinical manifestations, including prolonged fever (>2 weeks), malaise, neuroretinitis, encephalitis, erythema nodosum, hepatitis, fatigue, weight loss, and splenomegaly. Musculoskeletal manifestations are present in more than 10% of patients, are often severe, and may evolve into chronic forms that persist for more than a year. Myalgia and arthropathy are the most common manifestations. Myalgia has a mean duration of 4 weeks. Arthropathy, which has a mean duration of 5.5 weeks, is more common in female patients over age 20 years, affects large and medium joints (half being weight-bearing joints), and is associated with symmetrical erythema nodosum. Tendinitis, neuralgia, and osteomyelitis are less common, with incidences lower than 1%.

Ocular and Neurologic Manifestations

Parinaud oculoglandular syndrome is a self-limited conjunctivitis associated with preauricular lymphadenopathy. Other atypical manifestations include neurologic syndromes (meningoencephalitis, meningitis, neuroretinitis).[9] Encephalopathy may occur in 2 to 4% of patients with cat-scratch disease,[10] mainly adolescents and adults. Patients usually have persistent headaches with or without fever and may develop seizures. Acute neurologic disorders, which

may range from self-limited nuchal rigidity to pupillary dilation or aphasia and hemiplegia, can persist for several weeks to months.

Neuroretinitis most commonly is manifested as papilledema associated with macular exudates that cause stellar retinitis. Neuroretinitis can present as a sudden unilateral loss of visual acuity.[11] *B. grahamii* and *B. quintana* also can cause nongranulomatous or granulomatous uveitis.[12]

BACTEREMIA AND ENDOCARDITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

B. quintana, B. henselae, B. alsatica, B. vinsonii subsp. *Berkhoffii, B. elizabethae*, and "*Candidatus* Bartonella mayotimonensis" are common causes of blood culture–negative endocarditis (Chapter 61). Sporadic cases of endocarditis have also been associated with *B. koehlerae, B. vinsonii* subsp. *Berkhoffii, B. vinsonii* subsp. *Arupensis, B. elizabethae, B. alsatica*, and "*Candidatus* Bartonella mayotimonensis." Patients with endocarditis usually have preexisting heart valve disease that promotes the development of infective endocarditis. Endocarditis caused by *Bartonella* species exhibits slight inflammation, with a few inflammatory mononuclear cells and small vegetations; the bacteria are seen extracellularly in dense immunopositive clusters that are mainly included in vegetations and in the cytoplasm of neutrophils and macrophages.

CLINICAL MANIFESTATIONS

The most commonly identified agents of *Bartonella* endocarditis are *B. quintana*, followed by *B. henselae* and other *Bartonella* species. Patients appear to have chronic, blood culture–negative endocarditis, usually with fever (90%). Echocardiography reveals vegetations in 90%.[13] Infections with *B. henselae* are epidemiologically linked to close contact with cats or cat fleas and previous valvular heart disease, whereas *B. quintana* endocarditis is frequently described in patients who are homeless, have alcohol use disorder, and are infected with body lice but do not have previous valvular lesions. The onset is usually subacute, with some patients being afebrile at the time of admission. About 50% of patients have embolic phenomena.

VASCULOPROLIFERATIVE DISEASE: BACILLARY ANGIOMATOSIS, PELIOSIS HEPATIS, AND VERRUGA PERUANA

PATHOBIOLOGY

Bartonella species have the ability to cause vasculoproliferative lesions through a process of pathologic angiogenesis that results in the formation of new capillaries from preexisting ones. These typical vasoproliferations can be expressed as skin lesions in bacillary angiomatosis, which is caused by *B. quintana* and *B. henselae*, or as a cystic form in the liver and spleen in peliosis hepatis, which is caused only by *B. henselae*.

Bacillary angiomatosis, which is a neovascular proliferation that has been reported most commonly in patients who have acquired immunodeficiency syndrome (AIDS), involves the skin and lymph nodes; it occurs less frequently in patients with other causes of immunosuppression and only exceptionally in immunocompetent patients. In bacillary angiomatosis, lesions comprise proliferating endothelial cells, bacteria, and mixed infiltrates of macrophages/monocytes and polymorphonuclear neutrophils, thereby leading to chronic inflammation. Bacteria are clustered as aggregates both surrounding and within endothelial cells, thereby indicating that the vascular endothelium represents a target tissue for intracellular and extracellular colonization in vivo. On histologic evaluation, bacillary angiomatosis is a lobular proliferation of small blood vessels that contain endothelial cells and bacteria, usually seen in clusters when stained with Warthin-Starry.

As in bacillary angiomatosis, lesions of verruga peruana, which is the chronic form of Carrión disease, are characterized by lobular proliferations and atypical endothelial cells that form both relatively solid sheets and small, well-formed vessels with patent lumens. Lesions are typically infiltrated, thereby indicating a chronic inflammatory process.

CLINICAL MANIFESTATIONS

In bacillary angiomatosis, cutaneous lesions often arise in crops and can be subcutaneous or dermal nodules with red or purple papules millimeters to centimeters in diameter (Fig. 291-2). When cutaneous lesions are absent, the diagnosis is often difficult and delayed because signs of visceral involvement are usually nonspecific. The potentially systemic nature of bacillary angiomatosis is reflected by the involvement of brain, bone, lymph node, bone marrow, skeletal muscle, conjunctiva, and mucosal surfaces of the gastrointestinal and respiratory tracts.

Peliosis hepatis affects solid internal organs, primarily the liver, with reticuloendothelial elements. In the liver, it is defined as a vascular proliferation of sinusoidal hepatic capillaries, thereby resulting in blood-filled spaces. The spleen, abdominal lymph nodes, and bone marrow may also be involved.

FIGURE 291-2. Skin lesion of bacillary angiomatosis.

Following acute Oroya fever, patients usually develop angioproliferative cutaneous tumors called verruga peruana after a latent period ranging from weeks to months. The infection is characterized by benign cutaneous vascular lesions that typically consist of round papules, which are frequently pruritic and bleeding. The infection is accompanied by malaise and arthralgias. Skin lesions may change over time from miliary to nodular subcutaneous lesions to large mulaire lesions. These large lesions are often engorged with blood and prone to ulceration and bleeding. This eruptive phase clinically resembles Kaposi sarcoma or bacillary angiomatosis. However, it has a low morbidity, and there are no reports of mortality.

DIAGNOSIS OF *BARTONELLA* INFECTION

Molecular Detection Methods

Because of their slow growth and the lack of reproducible biochemical methods for their identification, *Bartonella* are best identified by molecular methods regardless of the species or site of infection. Direct detection and final identification of *Bartonella* species from blood, bodily fluids, and tissue specimens, including lymph node, cardiac valve, skin, and liver, can be achieved with high sensitivity by polymerase chain reaction (PCR) amplification and sequencing of various housekeeping genes.[14,15] PCR can also detect *Bartonella* at the species level from lymph nodes in cat-scratch disease, directly from cardiac valves in patients with endocarditis, and in specimens from patients with bacillary angiomatosis or peliosis hepatis.

Mass Spectrometry

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry is an alternative for species identification and is an accurate and reproducible alternative method for the rapid and inexpensive identification of *Bartonella* species. This technique is useful if the bacterium is cultivated in the laboratory.

Alternative Methods

Some patients may be suspected of having *Bartonella* infection but not have bacteremia or obvious accessible infective sites. In these patients, other methods for the diagnosis of *Bartonella* infection include serology,[16] microscopy, culture, direct immunofluorescence, and immunohistochemistry (Table 291-3).

Serology remains the most widely used method for the diagnosis of cat-scratch disease. By immunofluorescence assay, an immunoglobulin G titer of 1:64 or greater is considered positive for cat-scratch disease, whereas patients with endocarditis usually have higher antibody titers (≥1:800).

The diagnosis of Oroya fever is often based on the examination of a peripheral blood smear stained by Giemsa; the percentage of infected red blood cells is sufficiently high so that bacteria are visible. Similarly, *B. quintana* can be seen within red blood cells with the use of a specific monoclonal antibody by immunofluorescence and confocal microscopy (see Fig. 291-1). Microscopic examination after Warthin-Starry silver staining or immunohistochemistry of a cardiac valve or skin biopsy specimen is also confirmatory for the diagnosis of *Bartonella* organisms in patients with endocarditis and bacillary angiomatosis.

Despite its association with culture-negative endocarditis, *Bartonella* species can be recovered from the blood of bacteremic patients. Culture is also confirmatory for cardiac valves, as well as skin and liver biopsy specimens, but rarely for lymph nodes. Cultures are usually positive after 2 weeks of incubation, but up to 45 days may be necessary for primary isolation.

TABLE 291-3 LABORATORY METHODS FOR THE DIAGNOSIS OF *BARTONELLA* INFECTIONS

CLINICAL MANIFESTATION	SEROLOGY	CULTURE	MOLECULAR METHODS	IMMUNOHISTOCHEMISTRY (WARTHIN-STARRY STAIN)	MICROSCOPY FOR INTRAERYTHROCYTIC ORGANISM (GIEMSA OR IF)

Differential Diagnosis

The differential diagnosis of bacillary angiomatosis is Kaposi sarcoma (Chapter 187), but PCR testing or visualization of bacteria in the tissue specimen can help distinguish between these two entities. Trench fever may be confused mainly with typhus group rickettsiosis (Chapter 302), relapsing fever (Chapter 297), and malaria (Chapter 316). Cat-scratch disease may be confused with tularemia (Chapter 287), pyogenic lymphadenitis, mycobacterial infection (Chapters 299 and 300), and neoplasia.

TREATMENT

Trench Fever

Patients with *B. quintana* bacteremia should be treated with gentamicin (3 mg/kg body weight/day IV for 14 days) in combination with doxycycline (200 mg/day PO) for 28 days. Because the intraerythrocytic presence of *B. quintana* decreases antimicrobial efficacy, the duration of treatment is critical in trench fever.

Oroya Fever and Verruga Peruana

In Oroya fever, treatment with penicillin, streptomycin, or fluoroquinolones (e.g., tetracycline or erythromycin) produces rapid defervescence and disappearance of the organisms from the blood, usually within 24 hours. Because coinfection with *Salmonella* species is common, the recommended regimen is either ciprofloxacin (500 mg orally twice daily) plus ceftriaxone (2 g every 12 to 24 hours intravenously) for 10 days or chloramphenicol (500 mg orally or intravenously four times a day) for 14 days in combination with another antibiotic (especially a β-lactam compound; e.g., ampicillin 1 to 2 g intravenously every 4 to 6 hours depending on local resistance patterns or susceptibility testing).

Streptomycin (15 to 20 mg/kg/day intramuscularly for 10 days) is effective for verruga peruana, but oral rifampin (10 mg/kg/day orally for 14 days) has become the drug of choice for the treatment of eruptive-phase bartonellosis, even though rifampin treatment failures have been reported. Ciprofloxacin (500 mg orally twice daily for 7 to 10 days) is an alternative for multiple eruptive-phase lesions in adults.

Cat-Scratch Disease

Typical cat-scratch disease is a self-limited illness that resolves within 2 to 6 months and usually does not respond to therapy because the bacteria are not alive within necrotic lymph nodes. In cases of long-lasting lymphadenopathy, patients should be reassured that the disease is benign and will probably subside spontaneously. Management consists of analgesics for pain and prudent follow-up. However, azithromycin (500 mg PO on day 1 and 250 mg PO on days 2 to 5 as single daily doses) is an alternative for patients with large, bulky lymphadenopathy. If lymphadenopathy does not resolve, lymph nodes can be removed surgically.

For cat-scratch disease with manifestations beyond lymphadenopathy, data are limited regarding the benefit of specific antimicrobial therapy for immunocompetent patients. For neuroretinitis, the combination of doxycycline (100 mg PO or IV twice daily) with rifampin (300 mg PO twice daily) seems to promote disease resolution, improve visual acuity, reduce optic disc edema, and decrease the duration of disease.

Endocarditis

Patients with suspected or PCR-proven *Bartonella* endocarditis or proven *B. quintana* endocarditis should be treated with oral doxycycline (100 mg twice a day for 6 weeks) in combination with gentamicin (3 mg/kg/day in one intravenous daily dose for 14 days).

Bacillary Angiomatosis and Peliosis Hepatis

Antibiotic treatment is warranted in all cases of *Bartonella*-associated vasculoproliferative disease. Erythromycin (500 mg four times daily) for 3 months is first-line therapy. The response of bacillary angiomatosis in immunocompromised patients can be dramatic, with resolution of palpable subcutaneous lesions within hours. Doxycycline (100 mg PO or IV twice daily) is an appropriate alternative. In patients with serious infections, erythromycin or doxycycline can be used in combination with rifampin (300 mg PO twice daily). The duration of therapy should be at least 3 months for bacillary angiomatosis and 4 months for peliosis hepatis. Peliosis hepatis responds slowly, and hepatic lesions continue to improve after several months of treatment, whereas cutaneous bacillary angiomatosis demonstrates improvement after 4 to 7 days of treatment and resolves after about 1 month of treatment. Relapses of peliosis hepatis and bacillary angiomatosis lesions after antibiotic treatment have been reported frequently, especially in immunocompromised patients who received shorter durations of therapy. Patients who relapse after the recommended treatment should be retreated for 4 to 6 months with erythromycin (500 mg PO four times daily) or doxycycline (100 mg PO twice daily), and patients who have repeated relapses should receive antibiotic therapy for as long as they are immunocompromised.

PREVENTION

Because arthropods play an important role in the transmission of feline *Bartonella* species to humans, rigorous arthropod control should be recommended by health care workers, particularly when advising immunocompromised individuals on the risks related to pet ownership. Cat fleas live on both cats and dogs and are best controlled by fumigating areas where these animals live.

PROGNOSIS

Without antibiotic treatment, Oroya fever causes death in up to 85% of untreated patients because of hemolysis or opportunistic infections, such as salmonellosis. With antibiotic treatment, however, the morality rate is rare.

Trench fever is not a fatal disease, but antibiotic treatment is required to avoid more severe disease, especially in patients who have abnormal heart valves and are at risk for endocarditis. Patients with *Bartonella* endocarditis have a higher death rate and undergo valvular surgery more frequently than patients with endocarditis caused by many other pathogens. Cat-scratch disease usually resolves spontaneously without any treatment in immunocompetent patients; however, patients who have complications or who are immunocompromised require antibiotic therapy to which they usually respond well, with a mortality rate of only about 1% even in hospitalized patients.[17] Without appropriate therapy, bacillary angiomatosis and peliosis hepatis spread systemically and can involve virtually any organ, sometimes with a fatal outcome. For these vasculoproliferative diseases, antibiotics are usually effective if they are given for a prolonged period, but cutaneous lesions in verruga peruana may benefit from surgery.

292 GRANULOMA INGUINALE (DONOVANOSIS)

WALTER BELDA, JR.

DEFINITION

Granuloma inguinale, also known as donovanosis, is a chronic and progressive bacterial ulcerative disease that predominantly affects the skin and mucous membranes of the genital, inguinal, perirectal, and anal regions, often associated with sexual transmission.

The Pathogen

Donovanosis is caused by *Klebsiella granulomatis*, which is a gram-negative, facultatively aerobic coccobacillus that is intracytoplasmic, immobile, and can be encapsulated. In lesions, these microorganisms are found inside macrophages in the form of small oval bodies called Donovan corpuscles, which are visible on Giemsa, Leishman, or Wright stains.

EPIDEMIOLOGY

Granuloma inguinale is uncommon but occurs more often in individuals with less access to soap and water for personal hygiene. It is endemic in tropical and subtropical countries such as Papua New Guinea, Australia, Argentina, and Brazil,[1] and sporadic cases are also reported in India and the Caribbean. In South Africa, no cases have been reported for more than a decade,[2] and the disease is very uncommon in the United States.

Donovanosis is generally considered to be primarily a sexually transmitted infection because the main clinical manifestations occur in the genital region. Infectivity is low, however, and multiple sexual contacts with infected partners are necessary to transmit the disease. It typically affects adults ages 20 to 40 years without a gender predilection. Congenital infection has been reported, but the few documented cases of perinatal transmission of donovanosis show an apparent predilection for otorhinolaryngologic structures.

PATHOBIOLOGY

In infected lesions, the dermis shows an inflammatory infiltrate consisting of lymphocytes, plasma cells, and histiocytes. Histiocytes are usually voluminous and have a vacuolar appearance, inside of which the inclusion corpuscles are usually easily identified with Giemsa, Leishman, or Wright stain.

CLINICAL MANIFESTATIONS

The incubation period of donovanosis is controversial, with studies indicating periods ranging from 2 weeks to 1 month. The lesion starts as a subcutaneous nodule or papule at the inoculation site and then evolves slowly to an erythematous, shiny, friable surface ulceration. In general, the lesions are not painful. Inguinal adenopathy is usually absent, but early-stage lesions that are located in the inguinal region simulate a bulb (pseudobulb).

The ulcerous forms can be lenticular in shape, with everted edges and a mild inflammatory reaction. Lesions grow slowly and become well defined, with a granular background, centrifugal and serpiginous in character, covered with a thick and fetid exudate. Ulcerative lesions have abundant secretions and bleed easily (Fig. 292-1). The lesion's edges are variable in appearance, firm in consistency, smooth, and may be flat or hypertrophic. The edges may eventually appear raised, thereby clearly defining the lesion and sometimes simulating a carcinomatous appearance.[3] Secondary bacterial infection can occur.

Lesions can multiply by self-inoculation, favored by the draining of the exudate. In the ulcerovegetating form, the abundant granulation tissue at the bottom of the ulcerated lesion exceeds the lesional contour and is a clinical form that bleeds very easily. The vegetating forms, in turn, lack secretions and usually present with small dimensions and well-defined borders.

Elephantiasis almost always occurs with long-lasting ulcerated forms of infection, which promote lymphatic alterations and create lymphedema as well as local stasis. As the lesions progress, they heal with intense fibrosis, which destroys the lymphatic pathways. These forms, which are found mainly on the female genitalia, are the most frequent complication of donovanosis. Squamous cell carcinomas of the vulva can develop in patients with long-standing, chronic disease.

FIGURE 292-1. Ulcerated nodule lesion with a granular fundus and bleeding located in the preputial balano sulcus.

Extra-genital locations can be a consequence of unusual sexual practices or be acquired by direct inoculation into the skin, particularly by contaminated fingers. Extra-genital lesions can occur in the gums, larynx, neck, armpits, chest, abdomen, joints, and bones, particularly the tibia. Hematogenous dissemination to internal organs, especially in immunocompromised patients, mainly involves the lungs, intestines, spleen, and liver.

DIAGNOSIS

The diagnosis is made by demonstrating Donovan bodies in material obtained from the lesions, using cytologic preparations and histology for confirmation. Direct microscopy is the fastest and most reliable diagnostic method. Infected material should be collected from the active granulation areas and inspected on a glass slide with Giemsa, Leishman, or Wright stains for direct visualization. The presence of cells with the bodies of Donovan is pathognomonic of the infection.

Polymerase chain reaction (PCR) for diagnosis is generally restricted to disease eradication programs. The culture of the etiologic agent in the yolk sac of a chicken embryo is extremely difficult and is not routinely available owing to its high cost, technical challenges, and high failure rate. No serologic tests are currently available to diagnose donovanosis. Biopsies should be performed on extensive lesions that have necrosis or sclerosis, to exclude the possibility of malignancy.

Differential Diagnosis

The differential diagnosis of donovanosis lesions includes primary syphilis (Chapter 295), flat condyloma (Chapter 344), chronic herpetic ulcers (Chapter 345), giant condyloma acuminata (Chapter 344), lymphogranuloma venereum (Chapter 294), and squamous cell carcinoma.[4,5] Other causes of ulcerous granulomatous lesions include cutaneous tuberculosis (Chapter 299), paracoccidioidomycosis (Chapter 308), and pyoderma gangrenosum (Chapter 407).

TREATMENT

The duration of antimicrobial treatment, regardless of the therapeutic regimen used, should continue at least until all lesions are completely healed. The current recommended first-line therapy is azithromycin (two 1-g tablets orally) per week for 3 weeks or until complete healing of the lesions. Alternatives, also for a least 3 weeks or until healing is complete, are doxycycline (200 mg orally per day), ciprofloxacin (750 mg orally twice a day), or sulfamethoxazole-trimethoprim (400/800 two tablets twice a day).[6] If lesions do not respond within the first several days, an aminoglycoside (e.g., gentamicin 1 mg/kg/day intravenously, three times a day for at least 21 days) should be added.

For refractory lesions or patients who are immunosuppressed or infected with the human immunodeficiency virus (HIV), the same therapeutic regimens are recommended, but parenteral therapy with gentamicin or chloramphenicol 500 mg orally four times a day should be considered instead in the most severe cases. For pregnant women, 500 mg of erythromycin should be given four times a day for at least 3 weeks.

Sexual contacts should be identified and examined, but asymptomatic contacts do not require treatment. For prophylactic treatment of neonates of mothers who have genital lesions of donovanosis, azithromycin (20 mg/kg/day for 3 consecutive days) is effective to avoid infection in the newborn.

ABSTRACT

Donovanosis is a chronic and progressive bacterial disease that affects the skin and mucous membranes of the genital and perigenital regions, often associated with sexual transmission and with low infectivity.

KEYWORDS

donovanosis
granuloma inguinal
sexually transmitted infection

PROGNOSIS

With prompt therapy, patients are usually cured. However, delayed diagnosis or treatment can lead to genital lymphedema, deforming and unsightly scarring, destruction of the body of the penis, and stenosis of the urethral, vaginal, and anal orifices. Malignant transformation to squamous cell carcinoma can occur.

MYCOPLASMA INFECTIONS

DAVID L. GOLDMAN

MYCOPLASMA PNEUMONIAE

DEFINITION

Mycoplasma organisms of the class Mollicutes are ubiquitous as pathogens and colonizing agents in the plant, animal, and insect kingdoms. They represent the smallest known free-living forms, but because they have fastidious growth requirements, they are difficult to culture. The presence of several species of *Mycoplasma* as commensals in animals and on human oral and genital mucosa frequently results in contamination of cell cultures. Such contamination led to the false implication of mycoplasmas as causative agents in many human diseases, both trivial and life-threatening. Of the human diseases that have proven to be due to mycoplasmas, pneumonia caused by *Mycoplasma pneumoniae* is by far the most clinically important.[1] This infection constitutes a significant proportion of cases previously classified as atypical pneumonia (Chapter 85), a nonspecific term for patchy pneumonias that generally do not respond to β-lactam antibiotics and have etiologic agents that are not easily cultured or visible on Gram stain. The term *atypical pneumonia* persists despite our increasing ability to identify specific etiologic agents, such as viruses, *Legionella* (Chapter 290), and *Chlamydophila* (Chapter 294).

The Pathogen

Mycoplasmas are short rods (10 × 200 nm) that have no cell wall and are bounded by a sterol-containing membrane. They are unaffected by cell wall–inhibiting antimicrobials such as β-lactams. In tissue culture, mycoplasmas are intracellular; but in vivo infection is primarily extracellular and affects epithelial cells and their organelles, such as cilia. Attachment to respiratory epithelium is by way of terminal adhesin proteins in specialized tip organelles.

EPIDEMIOLOGY

M. pneumoniae infection is spread person to person by respiratory droplets produced by coughing. Relatively close association with the index case appears to be required. The disease is usually introduced into families by a young child; in some studies, most of the infected adults were the parents of young children. As opposed to most viral respiratory infections, which are manifested 1 to 3 days after infection, *Mycoplasma* has an incubation period of 2 to 3 weeks. Therefore, a careful history showing several weeks between cases within a family may be an important clue to the mycoplasmal etiology. Organisms can be cultured from the sputum of infected individuals for weeks to months after effective treatment.

Most cases of *Mycoplasma* respiratory infection occur singly or as family outbreaks. However, in closed populations, such as military recruit camps and boarding schools, *Mycoplasma* can cause mini-epidemics and may be responsible for 25 to 75% of cases of pneumonia in such settings. Serologically based epidemiologic studies have documented the high incidence of *Mycoplasma* respiratory infection throughout the world. In the United States, it is estimated that each year at least one case of *Mycoplasma* pneumonia occurs for every 1000 persons, or more than 2 million cases annually. The incidence of *Mycoplasma* nonpneumonic respiratory infection may be 10 to 20 times greater. The highest attack rates are in individuals 5 to 20 years old, but *M. pneumoniae* infection can occur at any age.

As opposed to viral respiratory infections that peak in winter in temperate climates, a few studies have reported a peak incidence of *M. pneumoniae* outbreaks in the fall. Most surveys, however, show little or no seasonal predominance. Recurrent epidemic 4-year cycles have been described in several countries.

There is an age-related relationship of upper versus lower respiratory tract infection caused by *M. pneumoniae*. In children younger than 3 years, primarily upper respiratory tract infection develops, whereas bronchitis and pneumonia tend to occur in individuals ages 5 to 20 years. In older adults, pneumonia predominates.

PATHOBIOLOGY

Inoculation onto animal tracheal organ cultures is followed by ciliary damage and desquamation of surface epithelium. This latter effect is probably responsible for the hacking cough in *Mycoplasma* respiratory infection.

Several characteristics of *M. pneumoniae* probably play a direct role in the respiratory pathogenicity of this organism. The first is the affinity of *M. pneumoniae* for respiratory epithelial cells. Attachment appears to be between a terminal organelle at one end of the filamentous organism and a sialylated glycoprotein (I-FI) on the surface of both respiratory epithelium and erythrocytes that acts as a receptor. *M. pneumoniae* attaches to ciliated epithelial cells at the base of cilia and appears to produce most of its physiologic and cytolytic changes while remaining extracellular. Hydrogen peroxide produced by *M. pneumoniae* (the only human mycoplasma to do so) may be responsible for some in vivo cell damage, as it is for the hemolysis seen when the organisms are grown on blood agar plates. *Mycoplasma* infection activates T and B cells and induces many pro-inflammatory and anti-inflammatory cytokines as well as chemokines that may play a role in inflammation-related cell destruction. *M. pneumoniae* also secretes a community-acquired respiratory distress syndrome toxin, which binds surfactant protein and dysregulates host adenosine diphosphate (ADP) ribosylation. High levels of this toxin are produced during infection, and inoculation of this toxin in an animal model induces many of the pathologic features of *M. pneumoniae* infection, including vacuolization, cilostasis, and inflammatory changes.[2,3] Strain-specific elaboration of biofilms probably plays a role in protecting the organism from host immune cells and may decrease antimicrobial penetration. Functional asplenia and its attendant opsonization deficiencies may contribute to overwhelming infection with *M. pneumoniae*, as they do with *Streptococcus pneumoniae* infection.

In the course of *M. pneumoniae* infection, several classes of antibody are produced. Some of these fulfill the desired role of antibody production (i.e., neutralization of the agent), and others appear to be autoantibodies. The latter include agglutinins to lung, brain, cardiolipins, and smooth muscle. The best studied of these autoagglutinins are the cold isohemagglutinins, which are capable of clumping erythrocytes at 4° C.

These oligoclonal M-type immunoglobulins (IgM) cross-react with I antigens, one of the blood group antigens common to almost all mature human erythrocytes. High titers of the cold reactive antibody may cause hemolysis (presumably as a result of complement-activated, Coombs-positive erythrocyte destruction). As with other IgM antibodies, the *Mycoplasma*-induced cold agglutinins (Chapter 146) develop early in the disease (7 to 10 days) and are often present by the time the patient seeks medical attention. The titer of these agglutinins peaks at 2 to 3 weeks, and they persist for 2 to 3 months (Fig. 293-1).

CLINICAL MANIFESTATIONS

Although *M. pneumoniae* is predominantly an upper and lower respiratory tract infection, it can involve multiple organ systems.

Respiratory Infection

The majority of *M. pneumoniae* infections involve only the upper respiratory tract. After a 2- to 3-week incubation period, the disease has an insidious onset consisting of fever, malaise, headache, and cough (see Fig. 293-1). Cough is the clinical hallmark of *M. pneumoniae* infection. The frequency and severity of the cough increase during the next 1 to 2 days, and it may become debilitating. The gradual onset of symptoms is in contradistinction to the often fulminant manifestation of respiratory infection caused by influenza virus or adenovirus.[4]

In 5 to 10% of patients, depending somewhat on age, the infection progresses to tracheobronchitis or pneumonia. In these cases, the initial manifestations persist, and the cough becomes more severe. Although the pneumonia is generally mild and self-limited, fulminant and severe cases can occur.

The cough is usually relatively nonproductive but may yield white or occasionally blood-flecked sputum. With continued cough, parasternal chest

Serologically based epidemiologic studies have documented the high incidence of *Mycoplasma* respiratory infection throughout the world. In the United States, it is estimated that each year at least one case of *Mycoplasma* pneumonia occurs for every 1000 persons, or more than 2 million cases annually. The incidence of *Mycoplasma* nonpneumonic respiratory infection may be 10 to 20 times greater. The highest attack rates are in individuals 5 to 20 years old, but *M. pneumoniae* infection can occur at any age.

As opposed to viral respiratory infections that peak in winter in temperate climates, a few studies have reported a peak incidence of *M. pneumoniae* outbreaks in the fall. Most surveys, however, show little or no seasonal predominance. Recurrent epidemic 4-year cycles have been described in several countries.

There is an age-related relationship of upper versus lower respiratory tract infection caused by *M. pneumoniae*. In children younger than 3 years, primarily upper respiratory tract infection develops, whereas bronchitis and pneumonia tend to occur in individuals ages 5 to 20 years. In older adults, pneumonia predominates.

PATHOBIOLOGY

Inoculation onto animal tracheal organ cultures is followed by ciliary damage and desquamation of surface epithelium. This latter effect is probably responsible for the hacking cough in *Mycoplasma* respiratory infection.

Several characteristics of *M. pneumoniae* probably play a direct role in the respiratory pathogenicity of this organism. The first is the affinity of *M. pneumoniae* for respiratory epithelial cells. Attachment appears to be between a terminal organelle at one end of the filamentous organism and a sialylated glycoprotein (I-FI) on the surface of both respiratory epithelium and erythrocytes that acts as a receptor. *M. pneumoniae* attaches to ciliated epithelial cells at the base of cilia and appears to produce most of its physiologic and cytolytic changes while remaining extracellular. Hydrogen peroxide produced by *M. pneumoniae* (the only human mycoplasma to do so) may be responsible for some in vivo cell damage, as it is for the hemolysis seen when the organisms are grown on blood agar plates. *Mycoplasma* infection activates T and B cells and induces many pro-inflammatory and anti-inflammatory cytokines as well as chemokines that may play a role in inflammation-related cell destruction. *M. pneumoniae* also secretes a community-acquired respiratory distress syndrome toxin, which binds surfactant protein and dysregulates host adenosine diphosphate (ADP) ribosylation. High levels of this toxin are produced during infection, and inoculation of this toxin in an animal model induces many of the pathologic features of *M. pneumoniae* infection, including vacuolization, cilostasis, and inflammatory changes.[2,3] Strain-specific elaboration of biofilms probably plays a role in protecting the organism from host immune cells and may decrease antimicrobial penetration. Functional asplenia and its attendant opsonization deficiencies may contribute to overwhelming infection with *M. pneumoniae*, as they do with *Streptococcus pneumoniae* infection.

In the course of *M. pneumoniae* infection, several classes of antibody are produced. Some of these fulfill the desired role of antibody production (i.e., neutralization of the agent), and others appear to be autoantibodies. The latter include agglutinins to lung, brain, cardiolipins, and smooth muscle. The best studied of these autoagglutinins are the cold isohemagglutinins, which are capable of clumping erythrocytes at 4° C.

These oligoclonal M-type immunoglobulins (IgM) cross-react with I antigens, one of the blood group antigens common to almost all mature human erythrocytes. High titers of the cold reactive antibody may cause hemolysis (presumably as a result of complement-activated, Coombs-positive erythrocyte destruction). As with other IgM antibodies, the *Mycoplasma*-induced cold agglutinins (Chapter 146) develop early in the disease (7 to 10 days) and are often present by the time the patient seeks medical attention. The titer of these agglutinins peaks at 2 to 3 weeks, and they persist for 2 to 3 months (Fig. 293-1).

CLINICAL MANIFESTATIONS

Although *M. pneumoniae* is predominantly an upper and lower respiratory tract infection, it can involve multiple organ systems.

Respiratory Infection

The majority of *M. pneumoniae* infections involve only the upper respiratory tract. After a 2- to 3-week incubation period, the disease has an insidious onset consisting of fever, malaise, headache, and cough (see Fig. 293-1). Cough is the clinical hallmark of *M. pneumoniae* infection. The frequency and severity of the cough increase during the next 1 to 2 days, and it may become debilitating. The gradual onset of symptoms is in contradistinction to the often fulminant manifestation of respiratory infection caused by influenza virus or adenovirus.[4]

In 5 to 10% of patients, depending somewhat on age, the infection progresses to tracheobronchitis or pneumonia. In these cases, the initial manifestations persist, and the cough becomes more severe. Although the pneumonia is generally mild and self-limited, fulminant and severe cases can occur.

The cough is usually relatively nonproductive but may yield white or occasionally blood-flecked sputum. With continued cough, parasternal chest

ABSTRACT

Mycoplasma pneumoniae is a leading cause of community-acquired respiratory infections in children and young adults. It can cause disease sporadically and as outbreaks in closed communities such as boarding schools and military recruit camps. Pneumonia secondary to this organism is remarkable for a paucity of auscultatory chest findings, and radiographic findings are nonpathognomonic. A host of extrapulmonary complications have been reported, but many of these may be coincidental because the underlying disease is very common. Diagnosis is usually made on clinical grounds, but nucleic acid–based assays provide excellent sensitivity and specificity. Disease is usually self-limited and rarely fatal. Because of the absence of a cell wall, β-lactam antibiotics are ineffective. Treatment with either macrolides or doxycycline shortens the clinical course. Other mycoplasmas causing human disease are also briefly discussed.

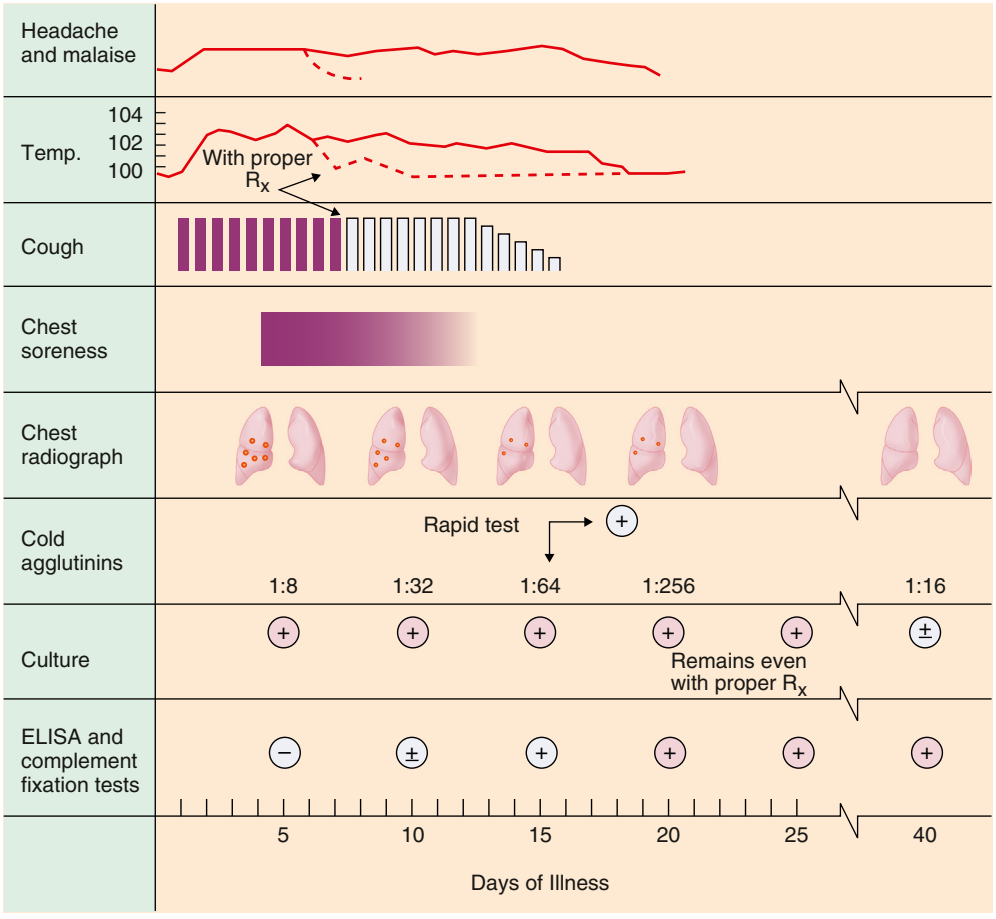

FIGURE 293-1. Major clinical and laboratory manifestations of mycoplasmal pneumonia. ELISA = enzyme-linked immunosorbent assay; R_x = treatment; Temp. = temperature. (Modified from Baum SG. Mycoplasmal infections. In: Wyngaarden JB, Smith LH Jr, eds. *Cecil Textbook of Medicine*. 17th ed. Philadelphia: Saunders; 1985:1506.)

soreness may develop as a result of muscle strain, but true pleuritic pain is unusual. Fever is usually at the level of 101° to 102° F and may be associated with chills. As opposed to pneumonia caused by *Streptococcus pneumoniae* (Chapter 268), that caused by *M. pneumoniae* rarely produces true shaking chills. In comparison to influenza (Chapter 332), which also can be manifested as an atypical pneumonia syndrome, myalgias and gastrointestinal complaints of nausea and vomiting are unusual. Diarrhea, sometimes a concomitant of adenoviral (Chapter 333) or *Legionella* (Chapter 290) pneumonia, is uncommon in *Mycoplasma* infection. Unfortunately, no clinical signs or symptoms can reliably differentiate *M. pneumoniae* infections from other community-acquired pneumonias.

On physical examination, the patient usually does not appear to be severely ill. Mycoplasma is the paradigm of the term *walking pneumonia*. The pharynx may be injected and erythematous, usually without the marked cervical adenopathy seen with group A streptococcal pharyngitis. Pharyngitis is uncommon, and myringitis and otitis are rare.

Examination of the chest in patients with *Mycoplasma* pneumonia is often unrevealing, even in patients with severe, productive cough. There may be no auscultative or percussive findings, or only minimal rales (crackles) may be present. Although wheezing can occur, the wheezing isolation is more suggestive of viral respiratory pathogens, such as respiratory syncytial virus (Chapter 330). *M. pneumoniae* is not a common pathogen in patients with preexisting chronic obstructive lung disease, and bacterial superinfection after *M. pneumoniae* respiratory infection is rare.

The radiographic finding of interstitial or patchy alveolar pneumonia does not differentiate *M. pneumoniae* from any of the other causes of atypical pneumonia, but the disparity between the physical findings and radiographic evidence of pneumonia in this condition may be the greatest of any of the atypical pneumonia syndromes (Fig. 293-2).

Pleural effusion (usually small) occurs in 5 to 25% of patients.[5] If effusion is present, thoracentesis reveals serous fluid that is exudative, with minimal inflammatory reaction. The cell differential count in the fluid is variable, and bloody effusions are rare. It is unusual to isolate *M. pneumoniae* from effusions when they do occur.

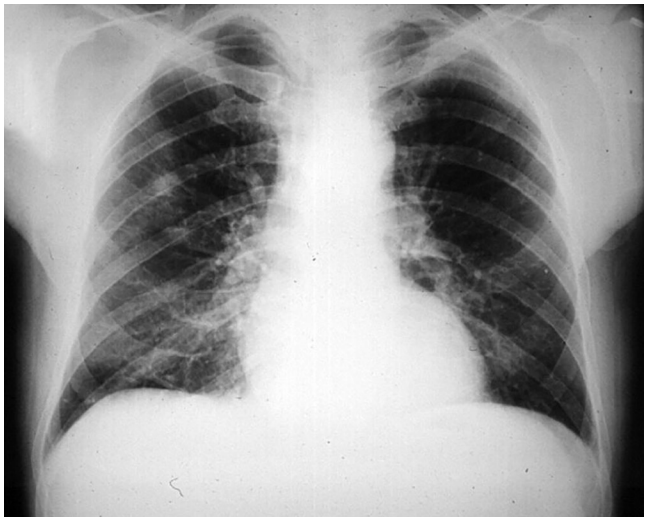

FIGURE 293-2. Chest radiograph showing moderate interstitial pneumonia due to *Mycoplasma pneumoniae* infection in a patient with a paucity of findings on chest auscultation.

Extrapulmonary Involvement

Extrapulmonary manifestations of *M. pneumoniae* infection can involve almost every organ system.

Dermatologic Involvement

Transient dermatologic conditions in conjunction with *Mycoplasma* pneumonia include macular, morbilliform, and papulovesicular eruptions, as well as erythema nodosum, urticaria, and a debilitating form of *M. pneumoniae*–associated mucositis without skin involvement.[6]

FIGURE 293-3. Stevens-Johnson syndrome in a child with *Mycoplasma* pneumonia. (From Baum SG. *Mycoplasma pneumoniae* and atypical pneumonia. In: Mandell GL, Bennett JE, Dolin R, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 6th ed. Philadelphia: Churchill Livingstone; 2005:2274.)

Up to 7% of patients with *Mycoplasma* pneumonia develop Stevens-Johnson syndrome (Fig. 293-3 and 403-8), which consists of erythematous vesicles, plaques, and bullae involving the skin, with particular localization at mucocutaneous junctions (Chapter 407). The conjunctivae as well as organs of the gastrointestinal and genitourinary tracts and the joints may also be involved. Stevens-Johnson syndrome can occur with or without prior antibiotic therapy, tends to occur in younger patients, and has a definite male preponderance (2 : 1 to 4 : 1). Most patients clear the lesions in 1 to 2 weeks without scarring unless impetiginization supervenes.

Cardiovascular Complications

Cardiac abnormalities are among the most commonly reported extrapulmonary manifestations of *M. pneumoniae* infection. Signs and symptoms suggesting involvement of the heart are arrhythmia, heart failure, chest pain, and electrocardiographic abnormalities, particularly conduction defects. Although cardiac abnormalities have been reported in as many as 10% of cases of *M. pneumoniae* infection, other reports indicate a much lower prevalence. Cardiac complications are more common with increasing age. They prolong the illness but rarely lead to death. The mechanism of heart damage is unknown, but *M. pneumoniae* can rarely be isolated from pericardial fluid.

Raynaud phenomenon (Chapter 66; Fig. 66-9) in *M. pneumoniae* may be related to the in vivo action of cold agglutinins. Other reported vascular complications in *M. pneumoniae* infection include internal carotid artery occlusion and cerebral infarction.[7]

Neurologic Complications

Neurologic complications are rare (about 0.1% of patients). Aseptic meningitis (Chapter 381), acute disseminated encephalomyelitis (Chapter 383), transverse myelitis (Chapter 369), brain stem dysfunction, posterior reversible encephalopathy syndrome, Guillain-Barré syndrome (Chapter 388), cerebral ataxia (Chapter 379), and peripheral neuropathy (Chapter 388) have all been reported. In patients with neurologic involvement, cerebrospinal fluid (CSF) findings are variable, but the cellular response is usually minimal, with slightly elevated protein level and normal to slightly depressed glucose concentration. Most often, the diagnosis of *Mycoplasma*-related central nervous system involvement is based on the exclusion of other causes, the presence of an antecedent or intercurrent respiratory illness, and a rise in antibody titer to *M. pneumoniae* in serum. Polymerase chain reaction (PCR) testing for *M. pneumoniae* in CSF is typically negative, thereby suggesting immune mechanisms of neural damage.

Hematologic, Musculoskeletal, and Renal Complications

The cold agglutinins generated by the immune response to *M. pneumoniae* can cause hemolytic anemia, which can range from mild to severe (Chapter 146).[8] Polyarthralgias are common in *Mycoplasma* pneumonia, but monoarticular or migratory arthritis is rare. Rhabdomyolysis (Chapter 99) may be associated with very high levels of muscle enzyme, interleukin-18, and tumor necrosis factor-α levels. Renal complications associated with immune complex deposition and high-titer cold agglutinins have been reported.

Sickle-Cell Disease

In patients with sickle cell disease or sickle-related hemoglobinopathies (Chapter 149), large pleural effusions and marked respiratory distress may develop. *M. pneumoniae* is also associated with acute chest syndrome, especially in children. Some sickle cell disease patients with *M. pneumoniae* infection and extremely high cold agglutinin titers may experience digital necrosis.

DIAGNOSIS

The diagnosis of *Mycoplasma* pneumonia is suspected primarily on clinical grounds. However, the very high incidence of *Mycoplasma* respiratory infection when it is studied epidemiologically in large populations compared with the rarity of individual sporadic diagnoses suggests this entity is seldom diagnosed in routine clinical practice.

The diagnosis can be confirmed by rapidly available, highly sensitive and specific PCR assays,[9,10] of nasopharyngeal, oropharyngeal, or sputum samples, typically as part of a respiratory panel that can detect multiple respiratory pathogens. A PCR-based assay for the determination of erythromycin resistance is available through the Centers for Disease Control and Prevention (CDC). The available antibody assays do not have acceptable sensitivity and specificity compared with PCR assays.

Gram staining of sputum reveals inflammatory cells but no predominant bacterial species. Culture of the organism in cell-free media requires weeks and is not widely available.

Cold Agglutinins

Immunoassays can detect cold agglutinins, which may help explain clinical manifestations such as Raynaud phenomenon. When testing for cold agglutinin, the results will not be available for at least a day, but a rapid version can be done at the bedside. In this test, 1 mL of the patient's blood is drawn into the tube used to collect specimens for prothrombin determination. Before cooling, examination shows a smooth coating of the tube by red cells. The blood is cooled to 4° C by placing it on liquid ice or in a standard refrigerator. After several minutes, the tube is examined for the presence of macroscopic erythrocyte agglutination. The tube is then rewarmed to 37° C in an incubator or by exposure to body heat and reexamined. The agglutination should dissociate at 37° C, and the appearance should be as it was before cooling. A positive result in the bedside test correlates with a laboratory titer of 1 : 64 and is highly suggestive of *Mycoplasma*-related cold agglutination. Other conditions associated with lower titers include mononucleosis caused by Epstein-Barr virus (Chapter 348), cytomegalovirus infection (Chapter 347), some other viral diseases, and lymphoma (Chapter 171). Nevertheless, a titer of 1 : 32 or greater is highly suggestive of infection with *M. pneumoniae*.

The presence of cold agglutinins can also artifactually give rise to macrocytic red blood cell indices by the Coulter counter method because of in vitro clumping of erythrocytes. When the phenomenon occurs, the red cell distribution width is high, indicative of heterogeneity in the measured red cell size.

TREATMENT

Despite the accuracy of PCR assays, most cases of *M. pneumoniae* infection are treated empirically in the ambulatory setting based on the clinical syndrome without definite microbiologic confirmation. Although pneumonia caused by *Mycoplasma* is usually self-limited and not life-threatening, antimicrobials as used for community-acquired pneumonia (Chapter 85) may shorten the duration of illness and, by reducing cough and the number of organisms per unit volume of sputum, may reduce the spread of infection to contacts. For mycoplasmal infection limited to the upper respiratory tract, antimicrobial therapy is not necessary.

Recommended therapy includes doxycycline (100 mg every 12 hours for 7 to 14 days) or azithromycin (500 mg on day 1 and then 250 mg every 24 hours to complete a 5-day course). Resistance to macrolides is not common in North America, but it is commonly encountered in Asia.[11,12] Other alternative antimicrobial options are fluoroquinolones (e.g., moxifloxacin, 400 mg daily or levofloxacin 750 mg daily) for 7 to 10 days.

In some pediatric studies, the addition of corticosteroids (e.g., prednisolone 1 mg/kg twice daily for 3 days then tapered over 1 week) has been reported to shorten the duration of symptoms in severe or refractory infections.[A1] However, corticosteroids are not recommended in adults with *M. pneumoniae* pneumonia. The treatment of cold agglutinin-associated hemolytic anemia is described in Chapter 146 (see Fig. 146-1).

PREVENTION

Vaccines using attenuated wild-type and temperature-sensitive mutant mycoplasmas are only about 50% for precipitating an antibody response, and volunteers who receive vaccine but do not mount an antibody response have more severe disease when rechallenged with wild-type *Mycoplasma* than do nonvaccinated persons. Prophylactic antibiotics decrease clinical disease in family members exposed to patients with *Mycoplasma,* but seroconversion is not prevented. In long-term care facilities, azithromycin prophylaxis (500-mg loading dose and 250 mg/day on days 2 through 5) can significantly reduce the secondary attack rate of *M. pneumoniae* infection.

PROGNOSIS

In many patients, *M. pneumoniae* infection is mild and self-limited. For more substantial illness, appropriate antibiotic therapy significantly shortens the duration of illness, but radiographic findings may take a week or longer to resolve, and organisms may continue to be cultured from sputum for several weeks after a complete course of clinically effective treatment.

Long-term sequelae are rare. Neurologic complications are usually reversible, but mortality in patients with central nervous system involvement is higher than in those without such involvement.

OTHER *MYCOPLASMA* SPECIES

Other proven *Mycoplasma* infections include those in the urogenital tract caused by *Ureaplasma* species, *M. hominis,* and *M. genitalium;* wound infections caused by *M. hominis;* and overwhelming systemic infection in immunocompromised patients caused by *Mycoplasma fermentans* (*incognitus* strain).

EPIDEMIOLOGY

Infections due to *Ureaplasma urealyticum, Ureaplasma parvum , M. hominis,* and *M. genitalium* are spread venereally, are not well documented (Table 293-1), and are difficult to culture but can be better identified by nucleic acid amplification testing. Their true incidence and prevalence are uncertain, as is their public health impact.

PATHOBIOLOGY

The genital mycoplasmas attach to cells using an adhesion protein as well as lipid-associated membrane proteins that adhere by way of toll-like receptors. Once within the cell, *M. genitalium* triggers elaboration of numerous cytokines that cause inflammation.

CLINICAL MANIFESTATIONS

Diseases attributed to *Ureaplasma* species include urinary tract infection with and without calculus formation.[13] This organism also has been implicated as a cause of low birthweight in neonates.

TABLE 293-1 SITES AND INFECTIONS RELATED TO HUMAN MYCOPLASMAS OTHER THAN *MYCOPLASMA PNEUMONIAE*

SUBGROUP	SITES OF ISOLATION	DISEASES	OCCURRENCE
M. hominis	GU tract (F > M)	Cervicitis, vaginitis, ?prostatitis	Common
	Conjunctivae (neonate)	Conjunctivitis	
	Blood (peripartum)	Peripartum sepsis	
	Surgical wounds, joints	Sternotomy infection, arthritis	
M. orale	Oropharynx	?	Common
M. salivarium	Oropharynx, gingiva	?Periodontal disease	Common
M. fermentans	GU tract, blood, tissues	Multisystem disease in AIDS	Uncommon
M. genitalium	GU tract	Urethritis, cervicitis, PID	Uncommon
Ureaplasma spp	GU tract	Urethritis, upper GU infection	Common

AIDS = acquired immunodeficiency syndrome; F = female; GU = genitourinary; M = male; PID = pelvic inflammatory disease; spp = multiple species.

M. genitalium infection can cause nongonococcal urethritis (Chapter 264)[14] in males and cervicitis and pelvic inflammatory disease (Chapters 264, 275, and 294) in females, in whom it leads in some cases to tubal factor infertility (Chapter 218), preterm birth, and spontaneous abortion. Chronic *M. genitalium* infection may enhance the acquisition of human immunodeficiency virus (HIV; Chapter 353) through increased shedding, and the prevalence of *M. genitalium* appears to be higher in patients with HIV than in the general population. Coinfection of *M. genitalium* with *Neisseria gonorrhoeae* (Chapter 275) is also noted,[15] and untreated *M. genitalium* is implicated in patients who have recurrent symptoms after standard treatment for a sexually transmitted infection (Chapter 264).

M. hominis, which is a common genitourinary and oral commensal, can cause endometritis and postpartum fever. It can also cause sternal wound infection after cardiothoracic surgery and has been implicated in arthritis in immunocompromised patients.

M. salivarium may be involved in periodontal disease. *M. fermentans, incognitus* strain can cause overwhelming multisystem involvement in immunocompromised patients.

DIAGNOSIS

PCR testing has enhanced the ability to detect *M. genitalium,*[16] and genital mycoplasmas, including *Ureaplasma* species and chlamydial organisms in secretions in a single panel, but the sensitivity and specificity of these tests appear to vary.

TREATMENT AND PROGNOSIS

Susceptibility testing for *M. hominis, M. genitalium,* and *Ureaplasma* spp is of limited clinical utility because these organisms grow slowly. As a result, the findings usually are not available when treatment decisions must be made.

M. hominis, unlike *M. pneumoniae,* is not sensitive to macrolides but is often sensitive to tetracyclines, clindamycin, and fluoroquinolones.[17] Treatment regimens for *M. hominis* are not well standardized but should take into account the severity of disease and the underlying immune status of the host. Uncomplicated genitourinary infections can be treated with doxycycline (100 mg orally twice a day for 7 days).

Increasing antimicrobial resistance also has been noted for *M. genitalium*, so the standard therapy for pelvic inflammatory disease (Chapter 264) is insufficient to cure these infections.[18,19] For infections due to *M. genitalium* (e.g., urethritis and cervicitis), a two-stage approach is recommended depending on the availability of susceptibility testing results. In the absence of susceptibility testing or documented resistance, patients should be treated with doxycycline (100 mg orally twice a day) for 7 days followed by moxifloxacin (400 mg orally once daily) for 7 days. For macrolide-susceptible organisms, treatment consists of doxycycline (100 mg orally twice a day) for 7 days followed by azithromycin (1 g orally initial dose, followed by 500 mg orally once daily for 3 additional days). Test of cure is not indicated. Testing and treatment (as for the index case) of all infected sexual partners is paramount to prevent transmission, if it has not already occurred, and reinfection.

PROGNOSIS

Prognosis of early disease without scarring of the cervix and fallopian tubes in women and urethra in men is relatively good. Prognosis also depends on the susceptibility of the offending organisms. It is highly likely that antimicrobial resistance will increase in the future, thereby complicating the treatment of infections due to these organisms and highlighting the need for improved susceptibility testing.

294 DISEASES CAUSED BY CHLAMYDIAE

HILARY E.L. RENO AND WILLIAM M. GEISLER

DEFINITION

Chlamydiae are obligate intracellular bacteria that cause a variety of human and animal diseases and much morbidity. Within the *Chlamydia* genus are now 11 validated species: *C. trachomatis, C. pneumoniae, C. psittaci, C. abortus, C. avium, C. caviae, C. felis, C. gallinacea, C. muridarum, C. pecorum,* and *C. suis.*[1] *C. trachomatis* is classified into a trachoma biovar and lymphogranuloma venereum (LGV) biovar.

The Pathogen

Chlamydiae have a gram-negative cell wall structure consisting of an outer membrane that contains lipopolysaccharide and an inner cytoplasmic membrane. The outer membrane contains a single 40-kD major protein (OmpA, also known as MOMP) and two cysteine-rich, minor outer membrane–associated proteins (OmcA and OmcB). Through intermolecular and intramolecular disulfide bonding, these proteins form a complex that provides structural rigidity.

Chlamydiae have small genomes (*C. trachomatis* contains 894 protein-coding genes, and *C. pneumoniae* contains 1052 genes). Most strains of *C. trachomatis* and some strains of *C. psittaci* contain a 7-kilobase cryptic plasmid.

Chlamydiae grow only within intracellular membrane-bound vacuoles, termed inclusions, which seclude the organism from extracellular and cytoplasmic environments. All chlamydiae share a distinct biphasic developmental cycle (Fig. 294-1) that includes an extracellular, metabolically inactive, infectious form (an elementary body) and an intracellular replicative form (a reticulate body). In vitro studies have shown that chlamydiae may enter a persistent state under certain conditions (e.g., penicillin treatment, challenge with certain cytokines, restriction of select nutrients) in which they have reduced metabolic activity and may be more refractory to antibiotic treatment. Chlamydiae are unable to synthesize adenosine triphosphate and therefore depend on the host cell for nutrients to meet their energy requirements.

PATHOBIOLOGY

Macrophages are the principal host cells for *C. psittaci* and *C. trachomatis* lymphogranuloma venereum biovar, whereas the principal host cells for *C. trachomatis* trachoma biovar and *C. pneumoniae* strains are columnar epithelial cells at mucosal sites. Host cell tropism correlates with the type of inflammation elicited by chlamydiae. The lymphogranuloma venereum biovar and *C. psittaci* produce granulomatous inflammation, characteristic of delayed hypersensitivity reactions. The trachoma biovar produces neutrophilic exudate during acute infection and submucosal mononuclear infiltration with lymphoid follicle formation during later stages of infection.

Chlamydiae elicit both humoral and cellular immune responses. Infection can persist or recur even after an adaptive immune response develops, thereby suggesting that the organism has evolved strategies for immune evasion. Persistent or recurrent infections can elicit inflammatory cellular immune responses that cause tissue injury.

CHLAMYDIAL DISEASES

Chlamydiae cause a wide range of human diseases (Table 294-1).

CHLAMYDIA TRACHOMATIS

C. trachomatis is a common cause of bacterial infection in humans and accounts for significant morbidity worldwide. *C. trachomatis* isolates have been differentiated into 18 major serovars (i.e., OmpA types) based on OmpA variations that can be identified on antigen cross-reactivity in the microimmunofluorescence test. The major diseases caused by *C. trachomatis* are trachoma, caused by serovars A, B, Ba, and C; sexually and perinatally transmitted diseases, caused by serovars D through K (and, rarely, serovars B and Ba); and sexually transmitted lymphogranuloma venereum, caused by serovars L1, L2, L2a, and L3. Sequencing of the *ompA* gene has led to the recognition of more OmpA variants, including L2b.

Trachoma is endemic in developing areas of the world. By comparison, sexually and perinatally transmitted *C. trachomatis*, including lymphogranuloma venereum chlamydial infections, occur worldwide.

TRACHOMA

EPIDEMIOLOGY

Trachoma is a chronic follicular conjunctivitis. The overall incidence is unknown, but the World Health Organization (WHO) estimates that 21.4 million people have active trachoma. Trachoma is endemic in more than 44 countries, and an estimated 137 million people are living in trachoma-endemic areas. Trachoma is especially common in poor areas of sub-Saharan Africa, where its prevalence in children may exceed 40%.

Trachoma is the most common preventable cause of blindness worldwide, affecting 1.9 million people by WHO estimates. Active trachoma often occurs in the first few years of life. The inflammation from recurrent or persistent trachoma can lead to conjunctival scarring, which can ultimately cause corneal

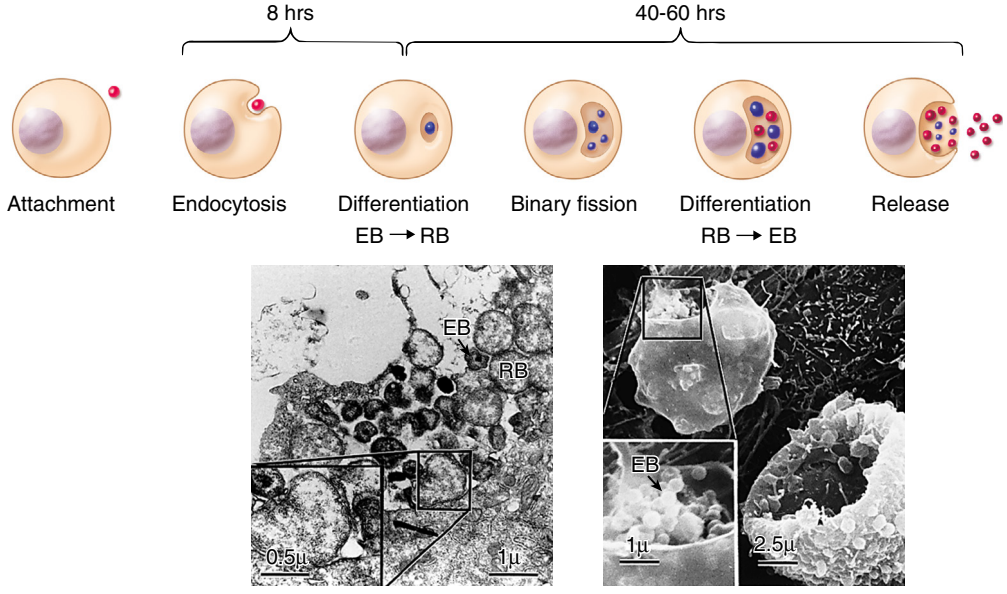

FIGURE 294-1. Developmental cycle of chlamydiae. The *top panel* shows the developmental cycle common to all chlamydiae. The *red dots* represent elementary bodies (EBs), and the *blue dots* represent reticulate bodies (RBs). Chlamydiae infect eukaryotic cells through multiple attachment mechanisms. After attachment, EBs enter the cell within a membrane-bound vacuole that remains unfused with lysosomes. EBs reorganize into RBs and asynchronously replicate 8 to 12 times, with a doubling time of 2 to 3 hours. At the conclusion of the growth cycle, RBs differentiate back to EBs, and each inclusion yields 100 to 1000 new infectious EBs. The *bottom left panel*, a transmission electron micrograph taken 40 hours after infection, shows the large RBs and the smaller EBs, which have a condensed nucleoid structure within their cytoplasm. The *bottom right panel*, a scanning electron micrograph taken 60 hours after infection, shows a membrane-bound vacuole containing many EBs exiting from an infected HeLa cell.

ABSTRACT

Chlamydiae are gram-negative obligate intracellular bacteria that grow only within intracellular vacuoles, called inclusions, which seclude the microorganism from extracellular and cytoplasmic environments. Major diseases caused by *Chlamydia trachomatis* are trachoma, the most common preventable cause of blindness worldwide; chlamydia, the most prevalent bacterial sexually transmitted infection in the United States; and lymphogranuloma venereum. Infections are difficult to diagnose clinically because most patients are asymptomatic, and even when symptoms or signs are present, they are nonspecific. Nucleic acid amplification testing is the recommended diagnostic method for clinical testing for chlamydia. *C. trachomatis* is susceptible to tetracyclines, macrolides, and select quinolones (levofloxacin and ofloxacin but not ciprofloxacin). Regimens vary depending on clinical manifestations.

TABLE 294-1 MAJOR DISEASES CAUSED BY CHLAMYDIAE IN HUMANS AND ASSOCIATED CLINICAL AND LABORATORY FEATURES

SPECIES	SEROVAR	DISEASE	TRANSMISSION ROUTE	DIAGNOSIS	PREVENTION
C. trachomatis	A–C	Trachoma	Fomites, eye-seeking flies	Clinical criteria or culture/NAAT	SAFE strategy
	D–K	Urethritis, cervicitis, proctitis, epididymitis, PID	Sexual contact	NAAT	Abstinence or monogamy, education, condoms, partner treatment
	D–K	Inclusion conjunctivitis, infant pneumonia	Perinatal contact	Culture, DFA, NAAT	Prenatal chlamydia screening: treat infected mothers
	L1–L3	Lymphogranuloma venereum	Sexual contact	NAAT with OmpA typing, culture, or serology	Abstinence or monogamy, education, condoms, partner treatment
C. pneumoniae	One	Upper respiratory infections, atypical pneumonia, asthma exacerbations	Respiratory droplet	Serology or culture/PCR	None
C. psittaci	Multiple	Psittacosis, atypical pneumonia, febrile illness	Aerosolized bird secretions, dust	Serology	Quarantine and chlortetracycline for imported birds, avoidance or precautions for at-risk subjects

DFA = direct fluorescent antibody test; NAAT = nucleic acid amplification test; OmpA = outer membrane protein A; PCR = polymerase chain reaction; PID = pelvic inflammatory disease; SAFE = World Health Organization's recommended strategy acronym for: surgery (for trichiasis), antimicrobials (periodic community-wide treatment), facial cleanliness, and environmental improvement.

damage and blindness later in life. The *C. trachomatis* serovars that produce trachoma are spread by direct contact with fingers or fomites (e.g., washcloths, handkerchiefs) that are contaminated with eye discharge from an infected person or by eye-seeking flies. Because of this mode of transmission, trachoma often clusters in households. Risk factors for trachoma include poor facial hygiene, limited access to water, poor sanitation, and proximity to other infected persons or to a heavy density of eye-seeking flies.

CLINICAL MANIFESTATIONS

The two stages of trachoma disease can overlap. Initially, trachoma begins as an inflammatory follicular conjunctivitis (i.e., active trachoma). On eversion of the upper eyelid, white to pale yellow lymphoid follicles can be visualized on the superior tarsal conjunctival surface, and papillae may be noted between follicles. Minimal watery or mucoid ocular discharge also may be seen. In more severe active trachoma, the conjunctiva can be thickened and edematous. Subsequently, conjunctival inflammation can progress to cause scarring of the upper tarsal conjunctiva (the cicatricial stage of disease). Scarring deforms the eyelid and can lead to an inward turning of the eyelashes, which can result in corneal abrasion (trichiasis). Over time, trichiasis causes corneal edema, ulceration, vascularization (pannus), scarring, and opacification. The corneal damage leads to decreased vision or blindness, mostly in young adults and middle-aged persons. Viral conjunctivitis (e.g., adenovirus; Chapter 333) presents similarly to active trachoma, but it is self-limited and usually resolves within a week. Trachoma can be complicated by superinfection with other bacterial pathogens (e.g., *Haemophilus influenzae*), which should be considered when purulent ocular discharge or significant inflammation of the bulbar conjunctiva is present.

DIAGNOSIS

Because the majority of trachoma cases occur in developing countries without access to laboratory testing or the necessary resources, trachoma is often diagnosed clinically on the basis of findings of active trachoma (follicles on the upper tarsal conjunctiva or pronounced inflammatory thickening of the tarsal conjunctiva) or cicatricial disease. When laboratories are available, detection of *C. trachomatis* by nucleic acid amplification is the most sensitive diagnostic test, provides definitive evidence of active trachoma, and may identify infection in subjects with minimal clinical evidence of active trachoma. For adults with late scarring, *C. trachomatis* usually is not detected by any of these assays.

TREATMENT

Active trachoma is best treated with a single-dose oral azithromycin (20 mg/kg; maximum of 1g),[A1] which also treats extraocular sites, such as the nasopharynx, that may be infected in young children. A less suitable alternative is tetracycline eye ointment (twice daily for 6 weeks), but its efficacy depends on adherence and can be limited by side effects, such as ocular irritation.

Surgical intervention is the only effective management for trichiasis. Eyelid rotation surgery prevents the eyelashes from abrading the cornea, thereby preventing blindness and other nonvisual symptoms. Unfortunately, trichiasis can recur after surgery in 10 to 30% of patients.

PREVENTION

The WHO is committed to eliminating blinding trachoma by 2030 and recommends that all countries with endemic trachoma adopt the SAFE strategy: surgery (for trichiasis), antimicrobials (periodic community-wide treatment), facial cleanliness, and environmental improvement. Mass treatment of a community with single-dose oral azithromycin is safe, can dramatically reduce the prevalence of infection for up to 1 year after treatment, and reduces mortality in children.[A2] Annual azithromycin treatment is recommended for trachoma-endemic areas. However, trachoma can recur after mass treatment, due in part to decreased herd immunity. Repeated mass treatment (every few months) provides herd protection to the entire community.[A3]

Mass antibiotic treatment is unlikely to be successful as the sole intervention for eliminating trachoma if other factors that facilitate transmission are not addressed. Face washing and good hygiene help reduce the risk for transmission through contact with fingers and flies. Better environmental conditions through measures that reduce the density of flies in households and the community, improved waste management, and access to clean water can also limit transmission. Improvement in socioeconomic conditions in a community correlates with a decline in the prevalence of trachoma.

SEXUALLY TRANSMITTED CHLAMYDIAL INFECTIONS

EPIDEMIOLOGY

Chlamydia is the most prevalent bacterial sexually transmitted infection in the United States. About 1.6 million infections were reported to the Centers for Disease Control and Prevention (CDC) in 2020.[2] The number of reported cases has increased since a chlamydia screening program was implemented,[3] but data also support a true increase in the number of cases. Taking into account underreporting and underscreening, the CDC estimates that more than 2.8 million new chlamydial infections occur annually in the United States.

Higher prevalence rates of chlamydia have been associated with younger age sexually active adolescents and young adults, as well as with new or multiple sexual partners. The prevalence is highest in the Southeastern United States. The prevalence of chlamydia is higher in women than in men, but it is unclear whether this higher prevalence is due to higher screening rates in women or whether women may be more susceptible to acquisition or persistence of infection. The estimated total cost attributable to chlamydial disease in the United States exceeds $691 million annually.[4] From a global perspective, WHO estimates that approximately 127 million new cases of chlamydia occur annually. In addition to the adverse effects on the reproductive health of women, chlamydia has a substantial impact on prenatal and perinatal outcomes, and it facilitates the transmission of human immunodeficiency virus (HIV).

CLINICAL MANIFESTATIONS

Urethritis

C. trachomatis is one of the most common causes of nongonococcal urethritis (Chapter 264) in men,[5] being responsible for 20 to 50% of cases. Although the majority of men with chlamydial urethritis do not have symptoms, studies in high-prevalence venues (e.g., sexually transmitted disease clinics) report

FIGURE 294-2. Clinical manifestations of genital *Chlamydia trachomatis* infection. A, Cloudy urethral discharge of urethritis. **B**, Urethral specimen Gram stain revealing nongonococcal urethritis findings: two or more polymorphonuclear cells per oil field (1000×) and the absence of intracellular gram-negative diplococci. **C**, Purulent endocervical discharge of mucopurulent cervicitis. (A, Courtesy James Sizemore, MD. B and C, From *Practitioner's Handbook for the Management of Sexually Transmitted Disease*. Retrieved from http://depts.washington.edu/handbook.)

that 40 to 60% of men with chlamydial urethritis have symptoms. The most frequent symptoms are urethral discomfort (itching or pain) with urination and urethral discharge. On examination, a mild to moderate amount of clear or cloudy/mucoid (rarely purulent) urethral discharge may be visualized (Fig. 294-2A). Urethral discharge sometimes becomes apparent only after stripping the urethra from the base of the penis to the glans; this manuever should be considered in men who report urethral symptoms without urethral discharge on initial inspection.

C. trachomatis urethritis also occurs in women, who may have no symptoms or present with an acute urethral syndrome characterized by dysuria, urinary frequency, and/or pyuria. This acute urethral syndrome mimics a urinary tract infection (Chapter 263), and chlamydia should be suspected in women with pyuria but negative urine nitrite and/or negative urine culture, especially in sexually active adolescents and young adults. Mild urethral discharge may be seen. Pelvic examination should be considered in women with suspected chlamydia urethritis to search for other clinical findings of chlamydia (e.g., cervicitis).

Epididymitis

Chlamydia can spread from the urethra to the epididymis and cause epididymitis,[6] which is found in up to 1% of chlamydia-infected men. In men younger than age 35 years, *C. trachomatis* is the principal cause of epididymitis; by comparison, complicated urinary tract infection (Chapter 263) with uropathogens is a more common cause in men older than age 35 years, especially in men with prostatic disorders (Chapter 114). Symptoms typically include unilateral testicular pain with scrotal erythema and swelling. On examination, palpable swelling and tenderness of the epididymis may be accompanied by testicular tenderness, scrotal erythema and swelling, urethral discharge, or hydrocele.

Cervicitis

C. trachomatis is responsible for up to 50% of cases of cervicitis. The majority of women with endocervical chlamydial infection are asymptomatic. When present, symptoms are often mild and nonspecific, such as vaginal discharge, intermenstrual vaginal bleeding, dysuria, and pain during intercourse (dyspareunia). On pelvic examination, up to 13% of women with asymptomatic cervical chlamydial infection have mucopurulent cervicitis (Fig. 294-2C), which is characterized by a purulent or cloudy endocervical discharge visible in the endocervical canal or on the tip of an endocervical swab. A similar proportion may have endocervical bleeding that is easily induced with passage of a swab through the cervical os. Nonspecific findings may include vaginal discharge and edematous ectopy (a darker red area of columnar epithelium visible on the face of the cervix).

Pelvic Inflammatory Disease

Chlamydia can spread from the cervix to the endometrium (causing endometritis), fallopian tubes (causing salpingitis), and peritoneum (causing peritonitis or perihepatitis).[7] These upper genital tract infections are collectively referred to as pelvic inflammatory disease (PID; Chapters 264 and 275). Estimates of the proportion of cervical chlamydial infections that progress to pelvic inflammatory disease vary greatly but are most commonly 10 to 35%. The majority of cases are subclinical or silent. Symptoms of pelvic inflammatory disease include pelvic or lower abdominal pain (especially during menses or the first 2 weeks of the menstrual cycle) and nausea. Fever is less common. Findings on physical examination include cervical motion tenderness and tenderness of the uterus or adnexa. Although most cases of chlamydial pelvic inflammatory disease are due to the natural progression of infection, they may also occur postpartum or after the termination of pregnancy.

Complications during Pregnancy

Some evidence suggests that genital chlamydial infection during pregnancy can lead to adverse outcomes, including preterm labor, low birthweight, miscarriage, and stillbirth,[8] but the data are conflicting.[9] Because the prevalence of chlamydia in pregnant adolescents and young adults in the United States can be high (>5%), the

potential morbidity associated with perinatally transmitted chlamydia is considerable. Neonates exposed to *C. trachomatis* during passage through the birth canal may develop inclusion conjunctivitis (about 20 to 40%) or pneumonia (about 10 to 20%).

Proctitis

Proctitis caused by non-lymphogranuloma venereum *C. trachomatis* OmpA types is usually asymptomatic. Subjects with acute symptomatic proctitis may report rectal pain or bleeding, tenesmus, pruritus, rectal discharge, or diarrhea. Anoscopy or sigmoidoscopy may reveal friable mucosa and a mucoid or mucopurulent discharge.

Conjunctivitis

An acute follicular conjunctivitis may rarely occur in adolescents or adults with genital chlamydial infection. The presumed mode of acquisition is autoinoculation with infected genital secretions. The typical clinical presentation is a subacute or indolent infection characterized by unilateral conjunctival redness, mucoid or mucopurulent ocular discharge, a foreign body sensation, and preauricular adenopathy.

Oropharyngeal Infection

C. trachomatis in the oropharynx of sexually active subjects is usually asymptomatic in most instances. *C. trachomatis* can be transmitted from oropharyngeal sites to the genital tract, providing rationale for treatment of oropharyngeal chlamydia. However, because oropharyngeal chlamydia prevalence is very low in most populations and the clinical significance of *C. trachomatis* detected in the oropharynx is unclear, routine oropharyngeal chlamydia screening is not recommended.

Lymphogranuloma Venereum

Lymphogranuloma venereum is a sexually transmitted infection caused by invasive *C. trachomatis* lymphogranuloma venereum OmpA serovars. In contrast to infection with other chlamydial strains, lymphogranuloma venereum is a more invasive systemic infection that involves lymphoid tissue (causing lymphadenitis) and can be ulcerative. Lymphogranuloma venereum is endemic in parts of Africa, India, Southeast Asia, South America, and the Caribbean. It also is a leading cause of proctitis and proctocolitis in men who have sex with men in Europe and North America.

In the early stage (3 to 30 days after acquisition) of genital lymphogranuloma venereum, a primary skin lesion or lesions may develop on the genital mucosa or adjacent skin in the form of a papule, ulcer, or herpetiform lesion. The lesion is usually asymptomatic and goes unnoticed, but it may be erosive; it heals quickly without scarring. Early genital lymphogranuloma venereum also may manifest as a nonspecific inflammatory syndrome (e.g., urethritis and cervicitis), similar to infection with other chlamydial strains. Two to four weeks later, genital lymphogranuloma can progress to an inguinal syndrome, characterized by painful, erythematous inguinal lymphadenopathy (buboes) and systemic manifestations, including fever, headache, arthralgias, myalgias, and leukocytosis. The buboes are commonly unilateral; about one third spontaneously rupture, drain pus, and can be complicated by fistulas or sinus tracts. Unruptured buboes usually heal.

Lymphogranuloma venereum may also manifest as an anogenital syndrome with invasive proctitis. Up to 20 to 30% of patients do not have symptoms, but common symptoms include fever, tenesmus, anal pruritus, and a rectal discharge that may be mucoid or, less commonly, mucopurulent or bloody. The rectal mucosa is friable, with multiple superficial ulcerations, and biopsy may reveal submucosal granulomas and crypt abscesses. These clinical and histopathologic findings resemble Crohn disease (Chapter 127).

DIAGNOSIS

C. trachomatis infections are difficult to diagnose clinically. A majority of infections are asymptomatic. Symptoms or signs, when present, are nonspecific. White blood cells are frequently found on a Gram stain of a urethral swab (Fig. 294-2B) or rectal swab or on a vaginal wet mount, but such findings cannot reliably distinguish chlamydia from other sexually transmitted infections (Chapter 264). A definitive diagnosis relies on detecting the organism using nucleic acid amplification tests, on a genital or rectal swab performed by a clinician, on noninvasively collected specimens (first-catch urine or a self-collected vaginal swab or rectal swab), or on infected material in patients with lymphogranuloma venereum.[10] Currently, serology is of limited clinical utility.

Nucleic acid amplification tests not only confirm the clinical diagnosis in patients with clinical manifestations, they also detect infection in symptom-free individuals. The CDC recommends annual chlamydia screening for sexually active women younger than age 25 years as well as for older women with risk factors (e.g., new or multiple sexual partners), men who have sex with men, and transgender persons.[A4,11,12] The recommended specimens for screening are first-catch urine in males and vaginal swabs in females. Chlamydia screening in women reduces the rate of pelvic inflammatory disease (Chapter 264). Universal chlamydia screening in men who have sex with women is not recommended. Selective chlamydia testing is also appropriate in venues with high prevalences (e.g., sexually transmitted infection clinics, correctional facilities), for high-risk men, or for men who have symptoms. However, although nucleic acid amplification tests can confirm the presence of *C. trachomatis*, they do not confirm the OmpA type; to confirm lymphogranuloma venereum, specific OmpA typing must be performed.

TREATMENT

C. trachomatis is susceptible to tetracyclines, macrolides, and select quinolones (ofloxacin and levofloxacin but not ciprofloxacin). The CDC's recommended treatment for uncomplicated chlamydia in nonpregnant individuals is doxycycline (100 mg orally twice daily for 7 days); azithromycin (1g orally in a single dose) is an alternative but has about a 5% lower cure rate for urogenital chlamydia compared with doxycycline.[A5] For rectal chlamydia, 1 week of doxycycline (100 mg twice daily) is also significantly more efficacious than single-dose azithromycin.[A6-A8] Another alternative treatment regimen for nonpregnant chlamydia-infected person is levofloxacin (500 mg orally once a day for 7 days).

However, adherence to the treatment is higher with single-dose azithromycin, so it may be considered for persons in whom adherence with the doxycycline regimen is a concern.[13] Because of its safety in pregnant women, azithromycin is also the recommended treatment for chlamydia-infected pregnant women.

C. trachomatis epididymitis and pelvic inflammatory disease should be treated with doxycycline (100 mg twice daily) for 10 and 14 days, respectively. Since treatment of these syndromes is usually empirical before test results are available (Chapter 264), ceftriaxone (500 mg intramuscularly in a single dose) is added to doxycycline to cover gonorrhea and metronidazole (500 mg orally twice daily for 14 days) is also added for anaerobic bacteria coverage in pelvic inflammatory disease.

Lymphogranuloma venereum should be treated with doxycycline (100 mg orally twice daily for 7 days) for 3 weeks. Some experts recommend azithromycin (1g orally weekly for 3 weeks) as an alternative.[A9] Infant chlamydial infections are treated with erythromycin base (50 mg/kg/day orally divided into four daily doses) for 14 days; data on other macrolides are limited, but a shorter treatment course with azithromycin (20 mg/kg/day orally) may be effective.

PREVENTION

Education and the provision of condoms are preventive measures that should accompany chlamydia treatment. Sexual partners (including current partners and partners in the preceding 60 days) and parents of chlamydia-infected infants should be evaluated and treated empirically. Expedited partner therapy, whereby chlamydia-infected patients are offered medication or a prescription to give to their sexual partners, or whereby clinicians provide medication to contacts without an examination, may reduce the risk for recurrent chlamydia. Patients and their partners should remain abstinent until treatment is completed.

Routine chlamydia screening may reduce the risk for pelvic inflammatory disease in sexually active young women. No chlamydia vaccine is available, but several are under investigation.

PROGNOSIS

A test of cure (4 weeks after completion of chlamydia treatment) is recommended routinely only for pregnant women but also should be considered if nonadherence with treatment is suspected or if symptoms persist. Recurrent chlamydia occurs in approximately 10 to 20% of chlamydia-infected persons within a few months of treatment, so repeated chlamydia testing is recommended approximately 3 months after treatment.

Outcomes of untreated genital chlamydia include spontaneous resolution (i.e., immune-mediated clearance in 10 to 40% of cases) and persisting infection; the latter may be subclinical or may progress to clinical manifestations (e.g., urethritis, cervicitis), which can remain uncomplicated or lead to a complication (e.g., pelvic inflammatory disease). Data in females suggest that up to 50% of genital chlamydial infections resolve after a year, but a small percentage (<10%) may persist.

Reactive arthritis, characterized by the classic triad of trigger infection (e.g., chlamydia), conjunctivitis, and arthritis, can complicate chlamydial infection (Chapter 244). Reactive arthritis cases triggered by chlamydia is more likely in males, with an estimated incidence of less than 1% of men who present with chlamydial urethritis.

Up to 15% of cases of chlamydial epididymitis are complicated by chronic pain (Chapter 26) that is usually idiopathic and often unresponsive to antibiotics. Other complications include decreased fertility and, rarely, testicular abscess. The long-term consequences of chlamydial pelvic inflammatory disease include infertility, ectopic pregnancy, and chronic pelvic pain.[14]

In the later stages of genital lymphogranuloma venereum infection, genital tract fibrosis can lead to complications such as infertility, elephantiasis, strictures, fistulas, and subcutaneous sclerosis. Late complications of rectal lymphogranuloma venereum include rectal strictures, anal fistulas, and lymphorrhoids (perianal growths of lymphatic tissue).

CHLAMYDIA PNEUMONIAE

Chlamydia pneumoniae[15] can cause community-acquired pneumonia (Chapter 85), upper respiratory tract infections (bronchitis, pharyngitis, laryngitis, and sinusitis), and exacerbations of chronic bronchitis and asthma. Possible links to atherosclerosis, Alzheimer disease, and multiple sclerosis are unproven.

EPIDEMIOLOGY

The majority of adults in the United States and other developed countries are seropositive for *C. pneumoniae*, up to 80% in some populations. Seroconversion often occurs during childhood or adolescence and may be subclinical. Studies incorporating culture or polymerase chain reaction (PCR) suggest that infection is not uncommon in children younger than 5 years. The CDC estimates there are 300,000 *C. pneumoniae* infections annually in the United States. *C. pneumoniae* causes an atypical pneumonia syndrome, with an estimated annual incidence of one case per 1000 population; epidemiologic studies suggest a 4-year cycle of increased pneumonia incidence. Up to 10% of community-acquired pneumonias are attributed to *C. pneumoniae*, and coinfection with other respiratory pathogens such as *Streptococcus pneumoniae* and *Mycoplasma pneumoniae* is not uncommon. The organism is believed to be acquired through the inhalation of infected respiratory droplets from persons with disease and possibly from symptom-free carriers. This mode of transmission can facilitate the spread of infection among household members and can cause epidemics in enclosed populations, such as persons in military barracks, nursing homes, and schools.

CLINICAL MANIFESTATIONS

Most *C. pneumoniae* infections occur in children, who often have mild clinical manifestations or do not have symptoms. Clinical manifestations are more evident in adults, especially the elderly, who have the highest incidence of *C. pneumoniae* pneumonia. *C. pneumoniae* causes an atypical pneumonia that is usually of mild to moderate severity. The incubation period may be several weeks, and the onset of disease is gradual. A nonproductive cough is usually present and is often preceded or accompanied by nasal congestion, sore throat, and hoarseness. Headache may occur in up to half of patients. Fever and dyspnea occur less commonly. *C. pneumoniae* may be manifested as isolated bronchitis, sinusitis, laryngitis, or nonexudative pharyngitis. On physical examination, localized pulmonary crackles or rhonchi are often heard.

In patients with pneumonia, chest radiography shows pneumonitis, most often evident as a single subsegmental lower lobe infiltrate. The leukocyte count is usually normal.

DIAGNOSIS

C. pneumoniae infection is usually diagnosed by polymerase chain reaction (PCR) testing of respiratory specimens as part of a diagnostic panel used in patients with community-acquired pneumonia. An alternative is serology showing a four-fold rise in IgG from paired sera or a single high IgM (>1:16) or IgG (>1:512) titer.

TREATMENT

The recommended treatment regimens for community-acquired pneumonia (Chapter 85) are effective for treating chlamydial pneumonia. Options for documented *C. pneumoniae* include azithromycin (500 mg on day 1 then 250 mg for 4 more days), doxycycline (100 mg twice daily for up to 14 days), clarithromycin (500 mg twice daily for 10 days), and levofloxacin (750 mg daily for 5 days). The clinical response to treatment may be slow, and some patients may need retreatment. Chronic *C. pneumoniae* infections may require even longer courses of treatment (e.g., 6 weeks), and azithromycin under the guidance of an expert has been suggested in this setting.

PROGNOSIS

The symptoms of *C. pneumoniae* upper respiratory tract infections may be protracted for several weeks, even with appropriate antibiotic treatment. Protective immunity may not occur after *C. pneumoniae* infection, so reinfection is common.

CHLAMYDIA PSITTACI

EPIDEMIOLOGY

C. psittaci naturally infects a variety of mammals and birds. *C. psittaci* strains appear to be host specific, and most human infections are linked to contact with an infected bird.[16] *C. psittaci* infection in humans is termed psittacosis, in part because exposure to psittacine birds (parrots, parakeets, and budgerigars) is commonly implicated in infections. However, because human cases have been linked to exposure to finches, pigeons, pheasants, ducks, turkeys, chickens, seagulls, and other birds, ornithosis may be a more appropriate term. Psittacosis disease in birds ranges from an asymptomatic carriage state to a mild symptomatic illness manifested by ruffled feathers, anorexia, shivering, dyspnea, diarrhea, or depression. Infected birds shed *C. psittaci* in urine, feces, or secretions from their beaks or eyes. Their feathers and surrounding environment become contaminated. Transmission to humans is primarily by inhalation of aerosolized bird secretions or dust. Infected birds may shed the organism for months. Person-to-person transmission rarely occurs.

Human psittacosis is a rare infection, due in part to antibiotic-laced bird feed and a mandated quarantine for imported birds. The number of cases of psittacosis in the United States has been stable for the past 10 years, with fewer than 10 confirmed cases reported annually; a larger number of cases are reported but not confirmed. Outbreaks have been attributable to occupational exposure in poultry processing plants. An outbreak of psittacosis occurred in 2014 in New South Wales from a novel source, exposure to abnormal equine fetal membranes. This outbreak suggests that horse exposure may be a potential risk factor for psittacosis and highlights the potential for humans to acquire the infection from other infected mammalian hosts.

CLINICAL MANIFESTATIONS

Psittacosis initially involves the lungs and then spreads to the reticuloendothelial system. The clinical spectrum of infection ranges from asymptomatic to fulminant, and clinical manifestations may resemble several other nonspecific febrile systemic illnesses, including Q fever (Chapter 302), typhoid fever (Chapter 284), and Legionnaires disease (Chapter 290). In contrast to *C. pneumoniae* pneumonia, psittacosis is more severe, with high fever and absent or minimal upper respiratory complaints.

After an incubation period of 5 to 14 days, some patients may present with a nonspecific virus-like illness or a mononucleosis-like syndrome. The presentation most suggestive of psittacosis is an acute febrile atypical pneumonia.[17] Patients initially have an abrupt onset of shaking chills and a temperature as high as 40.5° C. Temperature-pulse dissociation (i.e., elevated temperature with a normal pulse) may occur. Constitutional symptoms, including headache, myalgias, and arthralgias, are prominent. A cough, usually nonproductive, appears early in the illness and may accompany chest pain, which is usually nonpleuritic. Auscultation may be normal or reveal bilateral crackles. Chest radiograph findings are usually more dramatic than lung examination findings; the most common finding is single lower lobe consolidation, but multiple localized bronchopneumonic patches, diffuse ground-glass changes, and a miliary pattern have been described. Small pleural effusions may be seen.

Extrapulmonary findings frequently occur in psittacosis. Splenomegaly is common. A faint erythematous, blanching, maculopapular rash (Horder spots), resembling the rose spots of typhoid fever, can occur, as can erythema nodosum. Signs of hepatitis, endocarditis (culture negative), pericarditis, myocarditis, meningoencephalitis, hemolytic anemia, or disseminated intravascular coagulation may be noted. *C. psittaci* infection has also been associated with nongastrointestinal extranodal marginal zone lymphomas of mucosa-associated lymphoid tissue, including ocular and central nervous system sites.

DIAGNOSIS

Psittacosis should be suspected in patients who have a febrile illness (especially atypical pneumonia) and who report exposure to sick or imported birds or regular exposure to birds, including bird owners, pet shop workers, veterinarians, zookeepers, and poultry processing plant workers. The diagnosis is best made with serology. *C. psittaci* is a biocontainment level 3 agent because of its stability in the environment and aerosol transmission. Laboratory-acquired *C. psittaci* infections are well documented, so culture is discouraged. A serologic diagnosis of psittacosis is made by demonstrating (1) a four-fold or greater rise in complement-fixing or migration inhibitory factor antibodies against *C. psittaci* to a titer of at least 1:32 from acute to convalescent sera collected

at least 2 weeks apart (3 to 6 weeks is recommended) or (2) an IgM titer of 1:16 or greater against *C. psittaci* by migration inhibitory factor.

TREATMENT

Untreated psittacosis can be fatal, but mortality is rare with prompt antimicrobial treatment. Because of the delay in laboratory diagnosis, empirical therapy should be provided on the basis of clinical suspicion. The recommended treatment regimen, based on clinical experience, is either tetracycline (500 mg four times a day) or doxycycline (100 mg twice a day) for 10 to 21 days. Azithromycin (250 mg to 500 mg daily for 10 to 14 days) is a potential second-line alternative if patients cannot tolerate tetracycline drugs. Treatment of endocarditis includes prolonged antibiotic therapy and consideration of valve replacement.

PREVENTION

Epidemic psittacosis is preventable by a 30-day period of quarantine for all imported psittacine birds and their treatment with feed containing chlortetracycline. The U.S. Department of Agriculture recommends extending treatment for an additional 15 days after quarantine. Prevention of epidemic and endemic psittacosis also relies on avoidance of or protection from exposure to dust or body secretions from birds or their living areas, as well as avoidance of the handling of sick birds. Environmental sanitation is another important preventive measure because of the organism's resistance to drying.

PROGNOSIS

The response to treatment can be dramatic, with defervescence and marked clinical improvement within 24 to 48 hours. Full recovery may take several weeks, and relapse or reinfection can occur.

SYPHILIS AND NONSYPHILITIC TREPONEMATOSES

JODIE A. DIONNE AND KHALIL G. GHANEM

SYPHILIS

DEFINITION

Syphilis, which is a chronic infectious disease caused by the bacterium *Treponema pallidum* subspecies *pallidum*, is usually acquired by sexual contact with another infected individual. Syphilis is remarkable among infectious diseases for its large variety of clinical manifestations. If untreated, it progresses through primary, secondary, and tertiary stages. The early stages (i.e., primary and secondary), when lesions are present, are infectious. Spontaneous healing of early lesions is followed by a long latent period. In about 30% of untreated patients, late disease of the heart, central nervous system, or other organs may develop years after the initial infection. Syphilis remains a clinical challenge because of its protean manifestations.[1]

The Pathogen

The causative agent of syphilis, *T. pallidum* subspecies *pallidum*, is closely related to other pathogenic spirochetes, including those causing yaws (*T. pallidum* subspecies *pertenue*) and pinta (*Treponema carateum*). *T. pallidum* is a thin, helical bacterium approximately 0.15 µm wide and 6 to 15 µm long. The organism has 6 to 14 spirals and is tapered on either end. It is too thin to be seen by ordinary Gram stain microscopy but can be visualized in wet mounts by dark-field microscopy or in fixed specimens by silver stain or fluorescent antibody methods.

Unlike most bacteria, which have protein-rich outer membranes, the *T. pallidum* outer membrane appears to be composed of predominantly phospholipids, with few surface-exposed proteins. This structure may help syphilis progress despite the fact that non–surface-exposed internal antigens elicit a brisk antibody response that is the basis for serologic tests for the diagnosis and management of syphilis. Between the outer membrane and the peptidoglycan cell wall are six axial fibrils; three are attached at each end, and they overlap in the center of the organism. These fibrils are structurally and biochemically similar to flagella and are in part responsible for the organism's motility. All isolates studied are antigenically similar and susceptible to penicillin.

EPIDEMIOLOGY

The only known natural hosts for *T. pallidum* are humans and certain primates. With the exception of congenital syphilis, syphilis is acquired almost exclusively by intimate contact with the infectious lesions of primary or secondary syphilis (e.g., chancres, mucous patches, condylomata lata). Disease is usually acquired through sexual intercourse, including anogenital and orogenital intercourse. Occasional parenteral transmission still occurs in the setting of shared contaminated needles, although sexual transmission can be difficult to exclude in these cases. Transmission has been documented following organ transplantation. Transmission by contact with fomites is extremely uncommon. Occupational exposure among health care workers during direct examination of infectious skin lesions rarely leads to infection, and the last reported case of transfusion-transmitted syphilis in the United States occurred in 1966.

Syphilis is most common in large cities among sexually active individuals. The highest rate is found in men between the ages of 20 and 34 years. In the United States, regional prevalence is highest in the West and in the South.[2]

Syphilis spares no class, race, or group. U.S. syphilis rates are about five-fold greater in Blacks than in non-Hispanic Whites. In 2020, more than 80% of early syphilis cases occurred in men. When stratified by sexual partner information, about 50% of cases occurred among men who reported having sex with men.

The incidence of syphilis has generally declined worldwide for more than 100 years, with the exception of periods of war or social upheaval. With the introduction of penicillin treatment in 1943, primary and secondary syphilis declined rapidly to approximately 4 cases per 100,000 people in 1957. However, syphilis epidemics continue to occur, especially in men who have sex with other men, heterosexual individuals who use drugs of abuse, and adults living with HIV.

In 2020, the rate of reported primary and secondary syphilis in the United States was 11.9 cases per 100,000 population, more than five times the nadir rate of 2.1 cases per 100,000 in 2000. During that interval, primary and secondary syphilis rates increased among men of all ages, races, and ethnicities across all regions. Rates among women rose by about 1.5-fold between 2016 and 2020, mostly among women of ages 20 to 34 years who used injection drugs and methamphetamine, This increase has led to a four-fold increase in the rate of congenital syphilis, from 12.4 to 57.3 cases per 100,000 live births.[3] Patients with clinically evident late (i.e., tertiary) infection, particularly patients with cardiovascular or gummatous syphilis, are infrequently identified in high-income countries, likely because of the effectiveness of penicillin therapy for early stage syphilis.

PATHOBIOLOGY

T. pallidum may penetrate through normal mucosal membranes and minor abrasions on epithelial surfaces. The first lesions appear at the site of direct,

at least 2 weeks apart (3 to 6 weeks is recommended) or (2) an IgM titer of 1:16 or greater against *C. psittaci* by migration inhibitory factor.

TREATMENT

Untreated psittacosis can be fatal, but mortality is rare with prompt antimicrobial treatment. Because of the delay in laboratory diagnosis, empirical therapy should be provided on the basis of clinical suspicion. The recommended treatment regimen, based on clinical experience, is either tetracycline (500 mg four times a day) or doxycycline (100 mg twice a day) for 10 to 21 days. Azithromycin (250 mg to 500 mg daily for 10 to 14 days) is a potential second-line alternative if patients cannot tolerate tetracycline drugs. Treatment of endocarditis includes prolonged antibiotic therapy and consideration of valve replacement.

PREVENTION

Epidemic psittacosis is preventable by a 30-day period of quarantine for all imported psittacine birds and their treatment with feed containing chlortetracycline. The U.S. Department of Agriculture recommends extending treatment for an additional 15 days after quarantine. Prevention of epidemic and endemic psittacosis also relies on avoidance of or protection from exposure to dust or body secretions from birds or their living areas, as well as avoidance of the handling of sick birds. Environmental sanitation is another important preventive measure because of the organism's resistance to drying.

PROGNOSIS

The response to treatment can be dramatic, with defervescence and marked clinical improvement within 24 to 48 hours. Full recovery may take several weeks, and relapse or reinfection can occur.

SYPHILIS AND NONSYPHILITIC TREPONEMATOSES

JODIE A. DIONNE AND KHALIL G. GHANEM

SYPHILIS

DEFINITION

Syphilis, which is a chronic infectious disease caused by the bacterium *Treponema pallidum* subspecies *pallidum*, is usually acquired by sexual contact with another infected individual. Syphilis is remarkable among infectious diseases for its large variety of clinical manifestations. If untreated, it progresses through primary, secondary, and tertiary stages. The early stages (i.e., primary and secondary), when lesions are present, are infectious. Spontaneous healing of early lesions is followed by a long latent period. In about 30% of untreated patients, late disease of the heart, central nervous system, or other organs may develop years after the initial infection. Syphilis remains a clinical challenge because of its protean manifestations.[1]

The Pathogen

The causative agent of syphilis, *T. pallidum* subspecies *pallidum*, is closely related to other pathogenic spirochetes, including those causing yaws (*T. pallidum* subspecies *pertenue*) and pinta (*Treponema carateum*). *T. pallidum* is a thin, helical bacterium approximately 0.15 µm wide and 6 to 15 µm long. The organism has 6 to 14 spirals and is tapered on either end. It is too thin to be seen by ordinary Gram stain microscopy but can be visualized in wet mounts by dark-field microscopy or in fixed specimens by silver stain or fluorescent antibody methods.

Unlike most bacteria, which have protein-rich outer membranes, the *T. pallidum* outer membrane appears to be composed of predominantly phospholipids, with few surface-exposed proteins. This structure may help syphilis progress despite the fact that non–surface-exposed internal antigens elicit a brisk antibody response that is the basis for serologic tests for the diagnosis and management of syphilis. Between the outer membrane and the peptidoglycan cell wall are six axial fibrils; three are attached at each end, and they overlap in the center of the organism. These fibrils are structurally and biochemically similar to flagella and are in part responsible for the organism's motility. All isolates studied are antigenically similar and susceptible to penicillin.

EPIDEMIOLOGY

The only known natural hosts for *T. pallidum* are humans and certain primates. With the exception of congenital syphilis, syphilis is acquired almost exclusively by intimate contact with the infectious lesions of primary or secondary syphilis (e.g., chancres, mucous patches, condylomata lata). Disease is usually acquired through sexual intercourse, including anogenital and orogenital intercourse. Occasional parenteral transmission still occurs in the setting of shared contaminated needles, although sexual transmission can be difficult to exclude in these cases. Transmission has been documented following organ transplantation. Transmission by contact with fomites is extremely uncommon. Occupational exposure among health care workers during direct examination of infectious skin lesions rarely leads to infection, and the last reported case of transfusion-transmitted syphilis in the United States occurred in 1966.

Syphilis is most common in large cities among sexually active individuals. The highest rate is found in men between the ages of 20 and 34 years. In the United States, regional prevalence is highest in the West and in the South.[2]

Syphilis spares no class, race, or group. U.S. syphilis rates are about five-fold greater in Blacks than in non-Hispanic Whites. In 2020, more than 80% of early syphilis cases occurred in men. When stratified by sexual partner information, about 50% of cases occurred among men who reported having sex with men.

The incidence of syphilis has generally declined worldwide for more than 100 years, with the exception of periods of war or social upheaval. With the introduction of penicillin treatment in 1943, primary and secondary syphilis declined rapidly to approximately 4 cases per 100,000 people in 1957. ABSTRACT

Syphilis, which is a chronic infectious disease caused by the bacterium *Treponema pallidum* subspecies *pallidum*, is usually acquired by sexual contact with another infected individual. If untreated, it progresses through primary, secondary, and tertiary stages. The early stages (i.e., primary and secondary), when lesions are present, may be transmitted sexually. Spontaneous healing of early lesions is followed by a long latent period. In about 30% of untreated patients, late disease of the heart, central nervous system, or other organs may develop years after the initial infection. The nonsyphilitic treponematoses—yaws, endemic syphilis (previously known as bejel), and pinta—are the spirochetal diseases caused by *Treponema pallidum* subspecies (yaws and endemic syphilis) or by the closely related organism *Treponema carateum* (pinta). Like syphilis, the nonsyphilitic treponematoses are usually transmitted through direct contact with an infectious cutaneous or mucosal lesion.

primary inoculation. The minimal number of treponemes needed to establish infection is not known but may be as low as one. Multiplication of organisms is slow, with a division time in rabbits of approximately 33 hours. *T. pallidum* can be cultured, but is difficult to sustain in vitro, so culture is of no use in clinical practice. The slow growth of treponemes in humans probably accounts in part for the protracted nature of the illness, the relatively long incubation period, and the need for relatively long duration of therapy.

Syphilis is a systemic disease from the onset. Treponemes are capable of specific attachment to host cells. Most treponemes are found in the intercellular spaces, but they are occasionally seen within phagocytic cells. However, there is no evidence of prolonged intracellular survival of treponemes. *T. pallidum* is not known to produce toxins.

The primary pathologic lesion of syphilis is a focal endarteritis with an increase in adventitial cells, endothelial proliferation, and the presence of an inflammatory cuff around affected vessels. Lymphocytes, plasma cells, and monocytes predominate in the inflammatory lesion, and polymorphonuclear cells can be seen. The vessel lumen is frequently obliterated. With healing, considerable fibrosis develops. Treponemes can be identified in early syphilitic lesions as well as some late lesions, such as meningoencephalitis associated with general paresis. In general paresis, a perivascular and meningeal chronic inflammatory reaction includes thickening of the meninges, granular ependymitis, degeneration of the cortical parenchyma, and abundant spirochetes in tissues.

Granulomatous reaction is common in secondary and late syphilis. The granulomas are histologically nonspecific, and cases of syphilis have been incorrectly diagnosed as sarcoidosis or other granulomatous diseases. Human inoculation studies suggest that the pathogenesis of the gumma, which is a granulomatous lesion, involves hypersensitivity to small numbers of virulent treponemes introduced into a previously sensitized host.

Intracutaneous inoculation of partially purified antigens of *T. pallidum* into patients with syphilis in various stages has shown that delayed cellular hypersensitivity develops late in secondary syphilis and is uniformly present in latent syphilis. Patients with primary and secondary syphilis sometimes exhibit temporary hyporesponsiveness of lymphocytes to treponemal antigens, and the waxing and waning of lesions in early syphilis may depend on the balance between the development of effective cellular immunity as compared with the suppression of thymus-derived lymphocyte function.

The host responds to infection by producing numerous antibodies; in some instances, circulating immune complexes may be formed as well. For example, nephrotic syndrome (Chapter 107) has occasionally been recognized in secondary syphilis. Renal biopsy specimens from these patients show membranous glomerulonephritis characterized by focal subepithelial basement membrane deposits containing immunoglobulin G, C3, and treponemal antibody.

CLINICAL MANIFESTATIONS

Primary Syphilis

The incubation period from the time of exposure to the development of the primary lesion averages approximately 21 days (range, 10 to 90 days). Initially, a painless papule develops at the site of inoculation and soon breaks down to form a clean-based ulcer—the chancre—with raised, indurated margins (Fig. 295-1). The borders of the ulcer are raised, firm, and indurated. On occasion, secondary infections change the appearance of the ulcer and can cause the lesion to become painful. Most chancres are single, although multiple ulcers occur in up to 30% of persons. An untreated chancre persists for 2 to 6 weeks, heals spontaneously, and leaves a faint scar. The syphilitic chancre is usually associated with unilateral or bilateral regional lymphadenopathy. Regional lymph nodes are movable, discrete, and rubbery, but they may not be palpable if the chancre occurs in the cervix or rectum.

Chancres can occur at any site of inoculation by direct contact, and most occur in anogenital locations. Chancres can also be seen in the pharynx, on the tongue, around the lips, on the fingers, on the nipples, and other exposed areas. The morphology of the chancre depends in part on the location of the lesion and the host immune response. In previously infected individuals, chancres may be small and remain opular. Chancres of the finger may appear erosive and can be quite painful. Chancres located inside the female genital tract or anal canal are often missed unless clinical suspicion is high and a careful examination is performed.

Secondary Syphilis

If the initial lesion is not effectively treated, the natural history of syphilis infection (Fig. 295-2) is to progress to secondary syphilis between 4 and 8 weeks after the appearance of the primary chancre. Signs and symptoms of secondary syphilis include malaise, fever, headache, sore throat, and other systemic complaints. Most patients have generalized lymphadenopathy, including involvement of the epitrochlear nodes. Approximately 30% of patients have evidence of a healing chancre, although many patients (including a disproportionate number of women and men who have sex with men) give no history of a primary lesion.

At least 80% of patients with secondary syphilis have cutaneous or mucocutaneous lesions at some point in their illness. Usually, the diagnosis is suspected on the basis of the cutaneous eruption. The rash, which is often minimally symptomatic, tends to be faint and can be difficult to visualize, particularly on dark-skinned individuals; as a result, many patients with late syphilis do not recall having a rash. Syphilitic rashes are varied in appearance but have certain characteristic features. Typical lesions are widespread, have symmetrical distribution, and are pink, coppery, or dusky red in color. They are generally nonpruritic and are rarely vesicular or bullous in adults. Lesions usually become indurated after the early macular stage, and they frequently have a superficial scale (i.e., papulosquamous lesions). Skin lesions tend to be polymorphic and rounded and can leave long-term residual pigmentation or depigmentation.

Early macular lesions are typically seen on the trunk, followed by spread to the rest of the body. The face is often spared, except for the perioral area. Next, a papular rash appears that is usually generalized and characteristically marked on the palms and soles (Fig. 295-1B). These rashes are often associated with a superficial scale and may be hyperpigmented. Facial rashes may be pustular and can resemble acne vulgaris. On occasion, the scaling may be so prominent that it resembles psoriasis. Ulceration may occur and produce lesions resembling ecthyma. In malnourished or debilitated patients, extensive and destructive ulcerative lesions with a heaped-up crust may occur, the so-called rupial lesions. Lesions around the hair follicles may result in patchy alopecia of the beard or scalp.

Ringed or annular lesions may occur, especially around the face and particularly on dark-skinned individuals. A lesion at the angle of the mouth or the corner of the nose may have a central linear erosion, the so-called split papule.

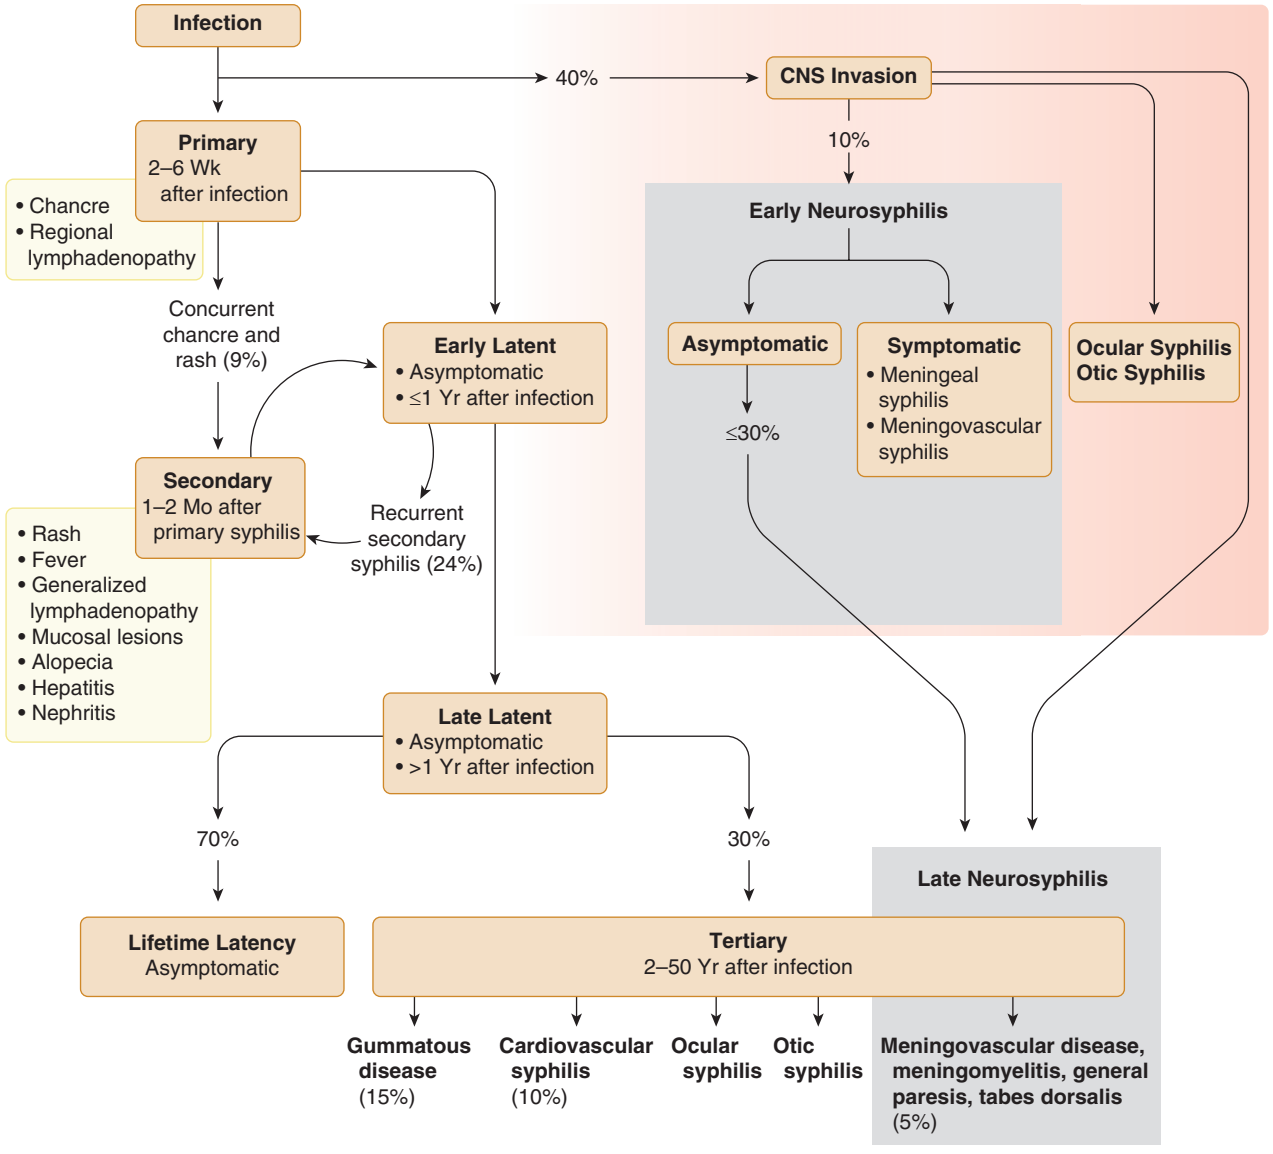

FIGURE 295-2. Natural history of syphilis infection. The time intervals between stages of syphilis are shown, along with the approximate percentages of persons progressing to the indicated stages. Invasion of the central nervous system (CNS) by treponemes may not be a necessary prerequisite for the development of certain forms of ocular syphilis. (Reproduced from Ghanem KG, Ram S, Rice PA. The modern epidemic of syphilis. *N Engl J Med*. 2020;382:845-854.)

In approximately 30% of secondary syphilis patients, so-called mucous patches (Fig. 295-1C) develop. These slightly raised, oval areas are covered by a grayish white membrane that, when raised, reveals a pink base that does not bleed. These lesions may be seen on the genitalia, mouth, tongue, palate, and pharynx.

In warm, moist areas such as the perineum, large, pale, flat-topped papules may coalesce to form condylomata lata (Fig. 295-1D). Papules may also be seen in the axilla and rarely occur in a generalized form. These papules are not to be confused with the common venereal warts (i.e., condylomata acuminata), which tend to be smaller, multiple, verrucous in appearance, and more sharply raised than condylomata lata. Like mucous patches, condylomata lata are highly infectious.

Other systemic manifestations of secondary syphilis include hepatitis, which has been reported in up to 10% of patients, and symptomatic gastritis. Jaundice is rare, but an elevated alkaline phosphatase level is common. Liver biopsy reveals small areas of focal necrosis and mononuclear infiltrate or periportal vasculitis. Spirochetes can often be visualized with silver stains. Periostitis with widespread lytic lesions of bone has been reported. An immune complex nephropathy with transient nephrotic syndrome (Chapter 107) has been documented. Between 10 and 30% of patients have cerebrospinal fluid (CSF) pleocytosis, but symptomatic meningitis is uncommon (<1%). Ocular involvement with iritis and anterior uveitis can also occur during the secondary stage (see Ocular Syphilis section). Secondary manifestations heal spontaneously within 2 to 6 weeks, and the infection then becomes latent.

Relapsing Syphilis

After resolution of the primary or secondary skin lesions, 20 to 30% of patients experience cutaneous recurrences. Rarely, the relapse takes the form of recurrence of the primary chancre. Recurrent lesions may be fewer or more firmly indurated than the initial lesions. Like the typical lesions of primary or secondary syphilis, relapsing infection can be transmitted to exposed sexual partners.

Latent Syphilis

By definition, latent syphilis is the stage at which there are no clinical signs of syphilis. Latency, which may last for a lifetime, is usually detected by reactive serologic tests for syphilis (see Diagnosis). Congenital syphilis must also be excluded before the diagnosis of latent syphilis can be made. Patients may or may not have a clinical history of earlier primary or secondary syphilis manifestations.

Latency has been divided into two stages: early and late. Most infectious relapses occur in the first year, and epidemiologic evidence shows that the most infectious period is during the first year after infection. Early latency is therefore defined as occurring within the first year after infection or as a newly reactive serologic test response for syphilis in an otherwise asymptomatic individual who has had a negative serologic test result within the preceding year. With the exception of vertical transmission (which can occur during any stage of syphilis in a pregnant woman), late latent syphilis and latent syphilis of unknown duration are considered noninfectious to sexual contacts.

Late benign syphilis (gumma)	4

*Some patients had more than one form of late syphilis.
†Autopsy diagnoses only.

Late (Tertiary) Syphilis

Without antibiotics, about one third of infected patients develop the destructive lesions of tertiary syphilis, involving the eyes, the central nervous system, the heart, and other organs, including the skin, years to decades after primary infection. In developed countries, however, tertiary syphilis is now very rare.

Late or tertiary syphilis (Table 295-1) is usually slowly progressive, although certain neurologic syndromes may have a sudden onset because of endarteritis and central nervous system thrombosis. Although any organ of the body may be involved, three main types of disease can be distinguished: late benign (gummatous), cardiovascular, and neurosyphilis.

Late Benign Syphilis

Syphilitic gummas, which are granulomas that typically develop 1 to 10 years after initial infection, can occur in any part of the body and are considered relatively benign since they respond rapidly to treatment. Gummas may be solitary or multiple and most often come to medical attention as space-occupying lesions. They are usually asymmetrical and are often grouped. Gummas may start as a superficial nodule or as a deeper lesion that breaks down to form punched-out ulcers. They are ordinarily indolent, slowly progressive, and indurated on palpation.

Gummas may involve the skin, bones, or deep visceral organs, particularly the respiratory and gastrointestinal tracts. Gummas of the stomach can masquerade as carcinoma of the stomach or lymphoma. Gummas of the liver can manifest with hepatosplenomegaly, anemia, fever, and jaundice. Skeletal gummas, which are most often found in long bones, skull, and clavicles, can present as nocturnal pain. Syphilitic gummas can resemble other chronic granulomatous diseases caused by tuberculosis (Chapter 299), sarcoidosis (Chapter 83), leprosy (Chapter 301), and deep fungal infections.

Cardiovascular Syphilis

Cardiovascular syphilis usually begins within 5 to 10 years of the initial infection but may not be manifested clinically until 20 to 30 years later. Cardiovascular syphilis does not occur after congenital infection.

The primary cardiovascular complications of syphilis are aortic aneurysm (Chapter 63), usually of the ascending aorta, and aortic insufficiency (Chapter 60), owing to aortic valve dilation (with normal valve cusps). In aortic insufficiency resulting from dilation of the aortic ring, the decrescendo murmur is often loudest along the right sternal margin. Less commonly, other large arteries may be affected, and involvement of the coronary ostia rarely results in coronary insufficiency. An aneurysm occasionally is manifested as a pulsating mass bulging through the anterior chest wall. Syphilitic aortitis may also involve the descending aorta proximal to the renal arteries.

Syphilitic aneurysms are typically saccular and do not lead to aortic dissection. Between 10 and 20% of patients with cardiovascular syphilis have coexistent neurosyphilis.

Neurosyphilis

Central nervous system involvement occurs throughout the natural history of syphilis. An estimated 1.8% of U.S. patients with early (primary, secondary, and early latent) syphilis have neurosyphilis, which may be found more often in patients who are living with HIV.[4]

Neurosyphilis[5] can be divided into five groups: asymptomatic, syphilitic meningitis, meningovascular syphilis, tabes dorsalis, and general paresis. Asymptomatic neurosyphilis can occur at any time, whereas syphilitic meningitis is most common during the secondary stage of infection. Meningovascular syphilis, tabes dorsalis, and general paresis are typically manifestations of late syphilis. The divisions are not absolute, and overlap between syndromes is typical.

Syphilitic Meningitis

Acute to subacute aseptic meningitis, which can occur at any time but usually occurs within the first year of infection, frequently involves the base of the brain and may result in unilateral or bilateral cranial nerve palsies. Mild aseptic meningitis may be relatively common, but severe disease occurs in only about 1.5% of untreated patients. Syphilitic meningitis typically resolves without treatment.

Meningovascular Syphilis

Some patients have sufficient endarteritis and perivascular inflammation to result in cerebrovascular thrombosis and infarction, on average at about 5 to 10 years after the initial infection but often earlier in patients with coexistent HIV infection. Patients frequently have associated aseptic meningitis. Most cerebrovascular accidents are not caused by syphilitic arteritis, even in patients who have a reactive serologic test result for syphilis. However, syphilis should be considered a potential cause in relatively young patients with a history of syphilis and without other risk factors for cerebrovascular disease.

General Paresis

General paresis, which is a chronic meningoencephalitis that results in the gradual and progressive loss of cortical function, typically occurs 10 to 20 years after the initial infection. In its early stages, general paresis results in nonspecific symptoms of early dementia, such as irritability, fatigue, headaches, forgetfulness, and personality changes. Later, symptoms include impaired memory, defective judgment, lack of insight, confusion, and often depression or marked elation. Patients may be delusional, and seizures sometimes occur. There may also be loss of other cortical functions, including paralysis or aphasia.

Physical signs are primarily those of the altered mental status. Cranial nerve palsies are uncommon, and optic atrophy is rare. The Argyll Robertson pupil is also uncommon (bilaterally small pupils that fail to constrict further in response to light but respond normally to accommodation; Chapter 392), but irregular or otherwise abnormal pupils can be seen. Peripheral reflexes are often increased.

Tabes Dorsalis

Tabes dorsalis is a slowly progressive, degenerative disease that involves the posterior columns and posterior roots of the spinal cord and results in progressive loss of peripheral reflexes, impairment of vibration and position sense, and progressive ataxia. The onset of tabes dorsalis is usually first noticed 20 to 30 years after the initial infection. Its cause is unclear, and spirochetes cannot be demonstrated in the posterior column or dorsal root. It is far less common now than in the prepenicillin era.

Sensory changes may lead to chronic destructive changes in the large joints of the affected limbs in advanced cases (i.e., Charcot joints). Urinary incontinence and impotence are common. Sudden and severely painful crises of uncertain origin are a characteristic part of the syndrome. Severe, sharp abdominal pain may lead to exploratory surgery. About 90% of patients have Argyll Robertson pupils (Chapter 392), and optic atrophy is seen in 20% of cases.

Ocular and Otic Syphilis

The eyes and ears may be affected during any stage of syphilis. Panuveitis and posterior uveitis are the most common ocular manifestations, but any portion of the eye may be affected.[6] Bilateral involvement is noted in 50 to 70% of involved cases. The clinical manifestations of ocular syphilis are broad and can include optic neuropathy, interstitial keratitis, and retinal vasculitis. In up to 70% of cases, concomitant CSF abnormalities consistent with neurosyphilis are detected.

Otosyphilis presents with sudden fluctuating or persistent sensorineural hearing loss or vestibular symptoms. Common complaints, in addition to hearing loss, include tinnitus and vertigo. In half the cases, both ears are affected. Unlike ocular syphilis, over 90% of persons with otosyphilis will have a normal CSF examination.

Syphilis-HIV Interactions

Syphilis, like other genital ulcer diseases, is associated with a two- to three-fold increased risk for acquisition of HIV infection (Chapter 353).[7] Presumably,

genital ulcers act as portals of entry through which HIV may more readily infect exposed individuals. As a result, HIV serologic testing 3 months after a diagnosis of syphilis is recommended for all patients. People living with HIV who acquire syphilis are somewhat more likely than people without HIV to present initially with secondary syphilis and coexistent chancres. Coinfected patients may also be at higher risk of developing neurologic complications, particularly early neurosyphilis.

Congenital Syphilis

Congenital syphilis, which results from the transplacental, hematogenous spread of syphilis from the mother to the fetus, can occur during any stage of pregnancy.[8] Less than 2000 cases of congenital syphilis are now reported annually in the United States,[9] with an estimated 660,000 annual cases worldwide.[10] The risk for fetal infection is highest in the early stages of untreated maternal syphilis and declines slowly thereafter, but the untreated mother can infect her fetus during at least the first 5 years of her infection. Untreated maternal infection may result in stillbirth, neonatal death, prematurity, or syndromes of early or late congenital syphilis in surviving infants.

Manifestations of early congenital syphilis are often seen in the perinatal period, but 60 to 90% of exposed neonates are asymptomatic. In the absence of treatment, clinical signs typically develop within the first 3 months of life. The disease resembles secondary syphilis in adults, except that the rash may be vesicular or bullous. The child often has rhinitis, hepatosplenomegaly, hemolytic anemia, jaundice, and pseudoparalysis (i.e., immobility of one or more extremities) as a result of painful osteochondritis.

Late congenital syphilis is defined as congenital syphilis diagnosed more than 2 years after birth. The disease may remain latent, with no manifestations of late damage. Cardiovascular alterations have not been observed in patients with congenital syphilis, but neurologic manifestations are common and may include eighth cranial nerve deafness and interstitial keratitis. Periostitis may result in prominent frontal bones of the skull, depression of the bridge of the nose (saddle nose), poor development of the maxilla, and anterior bowing of the tibia (saber shins). There may be late-onset arthritis of the knees (Clutton joints). The permanent dentition may show characteristic abnormalities known as Hutchinson teeth; the upper central incisors are widely spaced, centrally notched, and tapered in the manner of a screwdriver. The molars may show multiple poorly developed cusps (mulberry molars).

TABLE 295-2 SEROLOGIC TESTS FOR SYPHILIS

TYPE	USE
NONTREPONEMAL (ANTICARDIOLIPIN) ANTIBODIES	
VDRL (slide flocculation)	Screening, quantitation of response to treatment
RPR (circle card) (agglutination)	Screening, quantitation of response to treatment
SPECIFIC TREPONEMAL ANTIBODIES	
FTA-ABS (immunofluorescence with absorbed serum)	Confirmatory, diagnostic; not for routine screening
TP-PA (microhemagglutination)	Similar to FTA-ABS but can be quantified and automated
EIA and CIA	Confirmatory and increasingly used for screening; automated

CIA = chemiluminescence immunoassay; EIA = enzyme immunoassay; FTA-ABS = fluorescent treponemal antibody absorption test; RPR = rapid plasma regain test; TP-PA = *Treponema pallidum* particle agglutination; VDRL = Venereal Disease Research Laboratory.

TABLE 295-3 FREQUENCY OF POSITIVE SEROLOGIC TEST RESULTS IN UNTREATED SYPHILIS

STAGE	VDRL (%)	FTA-ABS (%)	TP-PA (%)
Primary	70	85	50-60
Secondary	99	100	100
Latent or late	70	98	98

FTA-ABS = fluorescent treponemal antibody absorption test; TP-PA = *Treponema pallidum* particle agglutination; VDRL = Venereal Disease Research Laboratory.

DIAGNOSIS

Dark-Field Examination

The most definitive means of diagnosis is finding typical spirochetes in lesions of early acquired or congenital syphilis. Dark-field examination is often positive in primary syphilis and in the moist mucosal lesions of secondary syphilis and congenital syphilis, but a single negative result is insufficient to exclude syphilis. However, few facilities have access to or skill with dark-field microscopes. Confusion may also arise because of the presence of spirochetes (e.g., *Treponema denticola*) that are morphologically indistinguishable from *T. pallidum* organisms in the mouth, particularly around the gingival margins.

Serologic Tests

Two basic types of serologic antibody tests (Table 295-2) are widely used to diagnose infection with *T. pallidum:* (1) nontreponemal tests to detect antibodies that react with diphosphatidylglycerol (cardiolipin), which is a normal component of many tissues,[11] and (2) tests that detect antibodies to specific treponemal antigens.[12]

Nontreponemal Tests

The standard tests to detect anticardiolipin antibody are the rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests, which are slide flocculation tests. The RPR and VDRL are readily quantified, so they are the tests of choice for monitoring patients' responses to treatment. The relative proportion of patients with a false-positive RPR or VDRL result depends on the prevalence of syphilis in the community; the lower the prevalence of syphilis, the higher the proportion of reactive RPR and VDRL test results from nonsyphilitic causes.

The RPR and VDRL test result begins to turn positive less than 1 week after onset of the chancre, so a nonreactive RPR or VDRL test result does not exclude primary syphilis, particularly if the lesion is less than 1 week old. The RPR or VDRL test result is positive in 99% of patients with secondary syphilis (Table 295-3). Patients with advanced HIV infection may have negative test results, and some patients have such high titers of antibody that they are in antibody excess; dilution of their serum paradoxically results in conversion of a negative test result to a positive one, the so-called prozone reaction. RPR and VDRL reactivity tends to diminish in later stages of syphilis, and only about 70% of patients with cardiovascular syphilis or late neurosyphilis have positive RPR or VDRL test results.

Although a single titer is diagnostic by itself, the quantitative titer of the RPR or VDRL test is somewhat useful in diagnosis and is quite useful for monitoring of the therapeutic response. RPR titers are highest during secondary syphilis, and most patients have titers of at least 1:16. Significant rises (fourfold or greater increase in titer, also referred to as a two-dilution increase) in paired sera strongly indicate acute syphilis. Most patients with false-positive RPR or VDRL test results have titers of less than 1:8.

Treponemal Tests

When the RPR or VDRL is used for screening, treponemal tests are required to confirm that the individual has antibodies to *T. pallidum*. These tests are sensitive and have a high degree of specificity, in that only approximately 1% of normal individuals have reactive treponemal test results. They are reactive in 85% of patients with primary syphilis, 99% with secondary syphilis, and at least 95% with late syphilis. They may therefore be the only test with a positive result in patients with cardiovascular or neurologic syphilis. For patients with late syphilis, treponemal test results often remain reactive for life, despite adequate therapy.

Options for treponemal testing include the fluorescent treponemal antibody absorption (FTA-ABS) test, as well as the newer treponemal enzyme immunoassays (EIAs) and chemiluminescence immunoassays (CIAs) that use cloned treponemal antigens to detect treponemal antibodies. The FTA-ABS test is reported in terms of relative brilliance of fluorescence, from borderline to 4 plus, with most laboratories reporting only test results with 2 plus or greater reactivity as positive. For patients lacking historical or clinical evidence of syphilis but with a reactive treponemal test result, the test should be repeated. Use of a different confirmatory treponemal test is recommended.

Because EIA and CIA serologic tests permit the screening of large numbers of sera and have performance characteristics (sensitivity, specificity, predictive values) similar to those of other treponemal tests, they have been increasingly used for syphilis screening, in contrast with the traditional approach that began with a nontreponemal (RPR or VDRL) screening test.[13,14] Persons with reactive treponemal antigen EIAs or CIAs should be tested with a quantitative RPR

or VDRL test to permit the use of that latter test to evaluate the subsequent response to therapy. It is not unusual for patients to have a reactive EIA or CIA test result for syphilis and a nonreactive RPR or VDRL test result. A substantial proportion of these EIA- or CIA-only positive test results are detecting long-standing, often previously treated, syphilis. Occasionally, they may detect very recent infection before RPR or VDRL test results become positive.

Point-of-care serologic tests for syphilis can detect treponemal antibodies, nontreponemal antibodies, or both. The performance characteristics of these tests vary but, in general, they are reasonably good, with a sensitivity as high as 98.5% and a specificity as high as 96%.[15]

Differential Diagnosis

The differential diagnosis of a genital ulcer (Chapter 264) includes genital herpes (Chapter 345), chancroid (Chapter 276), lymphogranuloma venereum (Chapter 294), and a number of other ulcerative processes.[16] Classically, herpetic ulcers are multiple, painful, superficial, and vesicular in their early stages. However, atypical manifestations may be indistinguishable from a syphilitic chancre. Genital herpes is much more common than syphilis and is now the most common cause of a "typical chancre" in North America. Syphilitic chancres may also be coinfected with herpes simplex virus in about 15% of cases. The ulcers of chancroid (Chapter 276) are usually painful, often multiple, and frequently exudative and nonindurated. Lymphogranuloma venereum (Chapter 294) may produce a small, papular lesion associated with regional adenopathy. Other conditions that must be distinguished include granuloma inguinale (Chapter 292), drug eruptions, carcinoma, superficial fungal infections (Chapter 405), traumatic lesions, and lichen planus (Chapter 405). In most cases, the final distinction is based on dark-field examination, which is positive only in syphilis, and on serologic test results.

The differential diagnosis of the skin lesions of secondary syphilis includes pityriasis rosea (Chapter 405), which can be differentiated by the occurrence of lesions along lines of skin cleavage and frequently by the presence of a herald patch. Drug eruptions, acute febrile exanthems (Chapter 406), psoriasis (Chapter 405), lichen planus (Chapter 405), scabies (Chapter 98), and other diseases must also be considered in some cases. A mucous patch may superficially resemble oral candidiasis (i.e., thrush). Infectious mononucleosis (Chapter 348) may appear similar to secondary syphilis, with sore throat, generalized adenopathy, hepatitis, and a generalized rash. Hepatitis (Chapter 134) and rash due to medication exposure may also simulate secondary syphilis.

False-Positive Serologic Test Results for Syphilis

The RPR or VDRL test result is reactive in patients with other treponemal diseases, such as pinta, yaws, and endemic syphilis. These nontreponemal tests may also be falsely reactive in persons who do not have treponemal infections based on a negative clinical history or negative results of serum treponemal tests.

For example, false-positive RPR or VDRL test results occur with low frequency in patients with atypical pneumonia (Chapter 85), malaria (Chapter 316), and other bacterial or viral infections, and they may occur after smallpox (Chapter 343) or other vaccinations, as well as during pregnancy. Chronic false-positive RPR test results (persisting >6 months) are relatively common in patients with autoimmune disorders such as systemic lupus erythematosus (Chapter 245), injection drug users (Chapter 365), patients with HIV (Chapter 359), patients with leprosy (Chapter 301), and the aged. Between 8 and 20% of patients with systemic lupus erythematosus have false-positive RPR or VDRL test results. Chronic false-positive RPR or VDRL test results in female patients 20 years or younger may indicate a risk for the future development of systemic lupus erythematosus, thyroiditis (Chapter 207), or other autoimmune disorders. As many as a third of injection drug users have false-positive RPR and VDRL test results. More than 1% of persons 70 years old and 10% of those older than 80 years also have low-titer, false-positive RPR or VDRL test results. In most cases of false-positive RPR or VDRL test results, the titer is less than 1:8, although a few patients with lymphoma (Chapters 171 and 172) and other diseases have very high-titer, false-positive results.

Treponemal test results can also be false-positive in chronic inflammatory diseases associated with hyperglobulinemia, including rheumatoid arthritis (Chapter 243) and biliary cirrhosis (Chapter 141), but such results are less likely than with an RPR or VDRL test. Lyme disease (Chapter 296) has been associated with false-positive treponemal tests, as has severe gingivitis. On occasion, reproducible positive treponemal test results are obtained in patients with no clinical or historical evidence of syphilis and no evidence of diseases typically associated with false-positive treponemal test results. If the diagnosis is in doubt and if the patient is not allergic to penicillin, it is often prudent to treat for possible syphilis.

Cardiac Syphilis

Asymptomatic aortitis (Chapter 63) is best diagnosed by visualizing linear calcifications in the wall of the ascending aorta by radiography, which may show an aneurysm that can be confirmed by echocardiography or computed tomographic (CT) scanning. The echocardiographic signs of syphilitic aortic insufficiency are the same as for aortic insufficiency of other causes (Chapter 60).

Neurosyphilis

Routine lumbar punctures to examine CSF are not indicated in neurologically asymptomatic, immunocompetent patients with early syphilis. Lumbar punctures are also not recommended for isolated ocular and/or otic signs and symptoms because the CSF parameters will be normal in up to 40 and 90% of patients, respectively. Although persons with HIV, particularly those with a CD4 count less than 350 cells/μL or an RPR titer ≥ 1:32, may be more likely to have CSF abnormalities consistent with neurosyphilis, there is no evidence that lumbar punctures in these asymptomatic patients lead to improved clinical outcomes.

Lumbar puncture is, however, indicated in all patients who have serologic evidence of syphilis and neurologic signs and symptoms. It is also indicated in patients who have cardiovascular syphilis or gummatous syphilis, even in the absence of neurologic signs or symptoms.[17] The VDRL and RPR tests do not perform equally for CSF, and only the VDRL, which has a sensitivity of about 50%, is recommended. Although numerous other processes can cause CSF pleocytosis or protein elevations, false-positive CSF VDRL test results are rare in the absence of a traumatic tap. A nonreactive CSF treponemal antibody test result may be useful to exclude the diagnosis, but the diagnosis of neurosyphilis should not be based solely on a reactive CSF treponemal test because of its lower specificity.

In syphilitic meningitis, the CSF shows a lymphocytic pleocytosis, with increased protein and usually normal glucose concentrations. The CSF VDRL test may be reactive. Rarely, the CSF glucose concentration is decreased.

In tabes dorsalis, the serum VDRL test is nonreactive in as many as 30 to 40% of patients, and 10 to 20% of patients have normal CSF VDRL results. Serum treponemal antibody tests are nearly always reactive. In general paresis, the CSF is nearly always abnormal, with a lymphocytic pleocytosis and an increased total protein concentration.

SCREENING AND PREVENTION

Annual syphilis screening is recommended in sexually active persons living with HIV. People who have HIV and are at high risk of syphilis infection should be screened as often as every 3 months. Screening is also recommended for persons with a previous syphilis infection, an infected sexual partner, or more than four sex partners in the preceding year.[18]

All patients with syphilis should be reported to public health authorities. In the absence of an effective vaccine, control of syphilis depends on finding and treating persons with infectious lesions of primary and secondary syphilis before they can transmit the disease, as well as finding and treating individuals with incubating syphilis before infectious lesions develop. All patients with early syphilis (primary, secondary, or early latent) should be carefully interviewed by qualified persons to determine the nature of their recent sexual contacts. Epidemiologic contact investigations for syphilis are limited when patients are not comfortable sharing sex partner details or report anonymous sex with partners identified through social media, and the numbers of sex partners identified and treated have declined in recent years. Approximately 16% of the named recent contacts of patients with early syphilis are found to have active, untreated syphilis on examination.

Treatment of the sexual contacts of patients with early syphilis with 2.4 million units of benzathine penicillin G intramuscularly is recommended even if the contacts are clinically and serologically normal on examination, because syphilis eventually develops in 30% of clinically normal untreated contacts. In general, preventive treatment is given to all sexual contacts in the past 90 days, although nearly all cases of syphilis in contacts develop within 60 days of exposure.

Doxycycline can be used as postexposure prophylaxis to decrease the incidence of syphilis (and/or other sexually transmitted infections).[A1] Pending large trials, however, doxycycline is not routinely recommended to prevent syphilis infection.

Congenital Syphilis

In pregnant women, a serologic test for syphilis should be performed universally at the first prenatal care visit, and it should be repeated at 28 weeks of gestation and at the time of delivery in women at high risk, including women

living in areas where syphilis is relatively common.[18,19] Adequate treatment of the mother before the 16th week of pregnancy usually prevents clinical illness in the neonate, but later treatment may not prevent late sequelae of the disease in the child.

TREATMENT

Treatment can be based on a positive dark-field examination or on serologic testing. *T. pallidum* is inhibited by less than 0.01 μg/mL of penicillin G. Because treponemes divide slowly and penicillin acts only on dividing cells, serum levels of penicillin must be maintained for many days (Table 295-4).[20,21]

Early Infectious Syphilis

Early syphilis (<1 year) can be treated with a single injection of 2.4 million units of benzathine penicillin G, which provides low but effective serum levels for about 2 weeks and cures approximately 95% of patients. It is not necessary to examine CSF at this stage because penicillin is highly effective at preventing the later development of neurosyphilis. The combination of oral amoxicillin 3 g plus probenecid is highly effective and tolerable for the treatment of syphilis in patients with HIV infection. For nonpregnant adult patients allergic to penicillin, 100 mg of doxycycline orally twice daily for 14 days is recommended.

Ceftriaxone (1.0 g intravenously once daily for 10 days) is noninferior to benzathine penicillin G (2.4 million units, intramuscularly, once weekly for 2 weeks) in nonpregnant, immunocompetent patients with early syphilis.[A2] Single-dose therapy with 2.0 g of azithromycin administered orally is also as effective as benzathine penicillin therapy in early syphilis,[A3] but treatment failures have been reported in persons with coexistent HIV infection. Particularly careful follow-up is necessary for patients treated with drugs other than penicillin because these regimens have been less than fully evaluated clinically and because patients may not be fully compliant with prolonged courses of oral therapy.

Syphilis of More than 1 Year in Duration

Prolonged therapy with intramuscular injections of 2.4 million units of benzathine penicillin G weekly for 3 weeks is recommended for the treatment of late latent syphilis and latent syphilis of unknown duration. Limited evidence suggests that treatment of latent syphilis with a total dose of 7.2 million units of benzathine penicillin during a 3-week period is curative, even if the patient has asymptomatic neurosyphilis. For nonpregnant adult patients allergic to penicillin, 100 mg of doxycycline orally twice daily for 28 days is recommended to treat late latent syphilis.

Cardiovascular Syphilis

Although there is no evidence that therapy with antimicrobial drugs is clinically beneficial in patients with cardiovascular syphilis, treatment is recommended to prevent further progression of disease and because approximately 15% of patients with cardiovascular syphilis have associated neurosyphilis.

Neurosyphilis, Ocular Syphilis, and Otosyphilis

Current guidelines recommend up to 24 million units of intravenous penicillin G per day for at least 10 days in all patients with neurosyphilis, ocular syphilis, or otosyphilis (see Table 295-4). General paresis responds well to penicillin therapy if it is administered early, although progressive neurologic decline may develop later in as many as a third of treated patients. Carbamazepine in doses of 400 to 800 mg/day can be used to treat the lightning pains of tabes dorsalis.

Syphilis in Pregnancy

Because of the risk to the fetus, evaluation and treatment of a pregnant RPR- or VDRL- reactive patient must be rapid, particularly for those patients first seen in the later stages of pregnancy. If a confirmatory treponemal test result is reactive and the patient has not been treated, penicillin should be administered in doses appropriate for early or late syphilis, as outlined earlier. Penicillin-allergic patients should undergo penicillin desensitization; in rare circumstances in which desensitization is not effective or tolerated, expert consultation is advised. Patients should not be treated with tetracycline or erythromycin because of potential toxicity (tetracycline) or lack of efficacy (erythromycin). For patients who are RPR or VDRL reactive but treponemal test negative and have no clinical signs of syphilis, treatment may be withheld; a quantitative RPR test and another treponemal test should be repeated in 4 weeks. If the treponemal titer has risen four-fold or more, or if clinical signs of syphilis have developed, the patient should be treated. If, after repeated examination, the diagnosis remains equivocal, the patient should be treated to prevent possible disease in the neonate. After treatment, a quantitative RPR titer should be monitored monthly; if it rises four-fold, the patient should be treated a second time.

Congenital Syphilis

Proper treatment of the mother usually prevents active congenital syphilis in the neonate. However, infected infants may be clinically normal at birth, and the infant may be seronegative if the mother's infection was acquired late in pregnancy. The infant should be treated at birth if the mother has received no treatment or inadequate treatment or has been treated with drugs other than penicillin, if the mother has not yet responded to possibly effective therapy, or if the infant cannot be carefully monitored for several months after birth. The infant's CSF should be examined before treatment. If the CSF is normal, the child can be treated with a single intramuscular injection of 50,000 units/kg (up to 2.4 million units) of benzathine penicillin G. If the CSF is abnormal, the infant should be treated with 50,000 units/kg of aqueous penicillin G given intramuscularly or intravenously twice daily for a minimum of 10 days. Alternatively, a single daily intramuscular injection of 50,000 units/kg of procaine penicillin may be given for 10 days. Antimicrobial agents other than penicillin are not recommended for treatment of congenital syphilis.

Jarisch-Herxheimer Reactions

Up to 60% of patients with early syphilis and a smaller (<10%) proportion of patients with later stages of syphilis experience a transient febrile reaction after therapy for syphilis. The pathogenesis is unclear, but it may be caused by the liberation of antigens from spirochetes, thereby resulting in a cytokine-release syndrome.

This reaction usually occurs in the first few hours after therapy, peaks at 6 to 8 hours, disappears within 12 to 24 hours of therapy, and is not related to the dose of penicillin. On occasion, Jarisch-Herxheimer reactions are mistaken for allergic reactions to syphilis therapy. Temperature elevation is usually low grade and is often associated with myalgia, headache, and malaise. The skin lesions of secondary syphilis are frequently exacerbated during the Jarisch-Herxheimer reaction, and cutaneous lesions that were not visible may become visible. The reaction is generally of no clinical significance and usually can be treated symptomatically with aspirin or a nonsteroidal anti-inflammatory drug (see Table 26-4). Premature labor may be a rare consequence in pregnant women.

TABLE 295-4 PENICILLIN TREATMENT FOR SYPHILIS AS RECOMMENDED BY THE CDC

	DOSAGE AND ADMINISTRATION[‡]	
INDICATIONS FOR SYPHILIS THERAPY*	**BENZATHINE PENICILLIN G**	**AQUEOUS BENZYLPENICILLIN G OR PROCAINE PENICILLIN G**
Primary, secondary, and early latent syphilis (<1 year); epidemiologic treatment	Total of 2.4 million units; single IM dose of two injections of 1.2 million units in one session	
Late latent (>1 year); cardiovascular syphilis, late benign (cutaneous, osseous, visceral gumma)	Total of 7.2 million units IM in doses of 2.4 million units at 7-day intervals during a 14-day period	
Symptomatic or asymptomatic neurosyphilis	2-4 million units aqueous (crystalline) penicillin G IV every 4 hours for at least 10 days	2-4 million units procaine penicillin IM daily and probenecid 500 mg orally four times daily, for 10-14 days
Congenital		
Infants	CSF normal: total of 50,000 units/kg IM in a single or divided dose at one session	CSF abnormal: total of 50,000 units/kg/day IM for 10 consecutive days[‡]
Older children	CSF normal: same as for early congenital syphilis, up to 2.4 million units	CSF abnormal: 200,000-300,000 units/kg/day aqueous crystalline penicillin IV for 10-14 days

*In pregnancy, treatment depends on the stage of syphilis.
[†]Individual doses can be divided for injection in each buttock to minimize discomfort.
[‡]For aqueous penicillin, give in two divided intravenous doses per day; for procaine penicillin, give as one daily dose intramuscularly.
CDC = U.S. Centers for Disease Control and Prevention; CSF = cerebrospinal fluid; IM = intramuscular; IV = intravenous.

PROGNOSIS

Follow-up Examinations

All HIV-seronegative patients with early or congenital syphilis should return for quantitative VDRL or RPR titers, and a clinical examination 6 and 12 months after treatment. For persons with HIV, serologic tests should be repeated at 3, 6, 9, and 12 months. Patients with late latent syphilis should also be examined 24 months after therapy.

In about 80 to 85% of patients with early (i.e., primary, secondary, or early latent) syphilis, quantitative RPR titers decline two or more dilutions (four-fold) by 12 months after therapy, but titers may take 24 months to decline following treatment of late-stage disease. In serofast patients (i.e., those whose titers do not decline appropriately), prolonged reactive RPR test results are associated with older age, lower initial RPR titers, prolonged infection, or more advanced stage (primary < secondary < early latent) infection. Retreatment of patients with serofast RPR results in the absence of evidence for reinfection has not been shown to impact short-term or long-term outcomes. Chronic, low-titer RPR reactivity after therapy is much more common in cases of late syphilis and should not be viewed with alarm. Treponemal test results may remain positive for years (even for a lifetime) despite adequate therapy. A four-fold or greater rise in RPR titer after therapy is sufficient evidence for repeated treatment. Patients with treated early syphilis are susceptible to reinfection, and many clinical and serologic relapses after therapy are probably reinfections.

Patients with neurosyphilis should be monitored with serologic tests for at least 3 years. Repeat CSF examinations are not recommended in immunocompetent persons and patients who are living with HIV and who are on effective antiretroviral therapy, provided that they demonstrate favorable clinical and serologic responses.

Antibiotic therapy should ultimately cure more than 95% of all patients with early or secondary syphilis, although treatment failures may occur more frequently in patients with concomitant HIV infection. In tabes dorsalis, penicillin usually arrests progression but does not reverse the symptoms. Meningovascular syphilis generally responds well, except for residual damage resulting from ischemic infarctions.

NONSYPHILITIC TREPONEMATOSES

DEFINITION

The nonsyphilitic treponematoses—yaws, endemic syphilis (previously known as bejel), and pinta—are the spirochetal diseases caused by *T. pallidum* subspecies (yaws and endemic syphilis) or by the closely related organism *Treponema carateum* (pinta). Like syphilis, the nonsyphilitic treponematoses are usually transmitted through direct contact with an infectious cutaneous or mucosal lesion. The natural history of the nonsyphilitic treponematoses also has a number of similarities to syphilis.

The Pathogen

Yaws is caused by *T. pallidum* subspecies *pertenue*, endemic syphilis is caused by *T. pallidum* subspecies *endemicum*, and pinta is caused by *T. carateum*. The *T. pallidum* subspecies causing nonsyphilitic treponematoses are closely related to *T. pallidum* subspecies *pallidum*, which causes venereal syphilis; there is a high degree (more than 99.8%) of DNA homology, and they share unique pathogen-restricted antigens. Like *T. pallidum*, these treponemes are spirochetal bacteria with helical structures and measure about 0.2 µm in diameter and 10 µm in length. They are visible by dark-field microscopy but cannot be cultivated for prolonged periods in vitro.

EPIDEMIOLOGY

Worldwide, the nonsyphilitic treponematoses are rare. The prevalence of these diseases was reduced dramatically in the 1950s by mass penicillin treatment campaigns, but the prevalence has increased subsequently, and as many as 2.5 million persons, 75% of whom are younger than age 15 years, are now infected worldwide. Yaws is prevalent in moist, humid regions, including rural areas of tropical Africa, the Americas, Southeast Asia, and the Western Pacific. Most cases are concentrated in three countries: Ghana, Papua New Guinea, and the Solomon Islands.[22] The highest incidence occurs in children between 2 and 5 years of age. Endemic syphilis occurs in more arid climates, including Africa, eastern Mediterranean countries, the Arabian Peninsula, Central Asia, and Australia. Pinta occurs in rural areas of tropical Central and South America and affects mostly older children and adolescents. Humans are the only known carriers of the nonsyphilitic treponematoses, although *T. pallidum* strains associated with genital lesions have been described in wild primates.[23]

The spirochetes enter the skin only after it is broken, such as by a scratch or an insect bite. Transmission is believed to occur by contact of the skin directly or by indirect contamination through hands or fomites; it is facilitated by conditions of poor personal hygiene and crowding.

PATHOBIOLOGY

Primary nodular or ulcerative lesions typically develop at sites of inoculation after an incubation period of several weeks. Untreated primary lesions serve as a source for local spread through scratching or for hematogenous dissemination, which gives rise to a secondary stage of infection characterized by the development of widespread manifestations involving the skin, lymph nodes, and bone or cartilage. Without therapy, the primary and secondary manifestations of infection resolve, and the infection becomes latent and detectable only with serologic testing. However, periodic recurrent secondary manifestations may occur for several years. A proportion of persons with long-standing untreated infection are at risk for late sequelae, which may include bone deformities, destruction of nasal cartilage, or chronic skin changes. Unlike syphilis, the nonsyphilitic treponematoses are primarily diseases of children, are not thought to be transmitted across the placenta, and may be less likely to invade the central nervous system to cause clinical disease.

CLINICAL MANIFESTATIONS

Yaws, the most common nonsyphilitic treponematosis, produces a skin papule at the inoculation site after an incubation period of 3 to 4 weeks. The most common sites are the legs and buttocks. The papule enlarges, ulcerates, and forms a serous crust from which treponemes can be recovered. Regional lymphadenitis may accompany the papule, which heals spontaneously within 6 months. A generalized secondary rash occurs before or after the initial lesion heals; this rash is also papular and is often covered with brown crusts. Relapsing crops of lesions can occur. Papillomas may result, and the plantar surfaces of the feet are involved with hyperkeratotic lesions. Periostitis of the long bones leads to tenderness, and fever may be present. Relapsing lesions of early yaws may occur during a period of several years and result in chronic ulcerations and destructive gummatous lesions affecting the skin and bones. *Haemophilus ducreyi*, the causative agent of chancroid (Chapter 276), also causes cutaneous ulcers, which are difficult to differentiate from those of yaws in children in yaws-endemic areas, such as Papua New Guinea.[24]

Endemic syphilis, which produces patches on the mucous membranes of the oral cavity and pharynx, can cause split papules at the mucocutaneous junction of the oral angles. Anal, genital, and other intertriginous skin areas can be affected by lesions that resemble secondary syphilis. Regional lymphadenitis is common, and generalized rashes are rare. Healing of these early lesions is followed by latency, manifested as seropositivity, or by late lesions that resemble gummatous tertiary syphilis. Lesions include nodular skin ulcers, bone deformities, and ulcerative lesions that can perforate the palate.

Pinta starts similarly as a cutaneous papule with regional lymphadenitis, followed by a generalized maculopapular eruption. One to 3 years after healing of the initial lesion, large hyperpigmented brown or blue macules develop; they subsequently lose their pigment and become white. The time required for lesions to pass through these stages varies, so the same patient may have coexisting areas of increased pigment and loss of pigment.

DIAGNOSIS

The clinical differentiation of cutaneous ulcers, which may be challenging, requires the integration of epidemiologic features, clinical findings, and supportive but not diagnostic laboratory test results. The skin lesions of the endemic treponematoses may resemble other cutaneous processes, including impetigo (Chapter 408), scabies (Chapter 98), cutaneous fungal infections (Chapter 405), chancroid (Chapter 276),[25] and other diseases. By dark-field microscopy, the causative spirochetes from early skin lesions can be observed directly, but dark-field microscopy is rarely available in settings where nonsyphilitic treponematoses are seen. No test is specific for any of the nonsyphilitic treponematoses, but serologic tests for syphilis detect cross-reacting antibodies in these diseases. The nontreponemal tests (RPR and VDRL) and the specific treponemal tests give positive results if serum is obtained at least 2 weeks after the lesions initially appear. Point-of-care tests also have adequate performance characteristics for the serologic detection of yaws.

PREVENTION

Whereas penicillin is effective for both treatment and prevention of infection, single-dose oral azithromycin, which is effective both for yaws and chancroid,

has simplified and expanded practical intervention strategies. For example, data from Papua New Guinea indicate that mass treatment with azithromycin could temporarily reduce the prevalence of active and latent yaws infection in endemic areas, and three rounds of mass drug administration are better than a single round.[A4]

TREATMENT AND PROGNOSIS

Single-dose, long-acting benzathine penicillin G, 1.2 million units intramuscularly, is effective in patients with early lesions.[26] For patients with late manifestations, this therapy should be repeated twice at approximately 7-day intervals. The early lesions heal rapidly, and most seropositive cases convert to seronegative status. Late destructive lesions take longer to show improvement.

Oral azithromycin, 30 mg/kg up to a maximal dose of 2.0 g, is as effective as penicillin for yaws,[A5] thereby providing the first readily administered, single-dose alternative to penicillin for treatment and prevention of nonsyphilitic treponematoses. Azithromycin resistance, while still rare, is concerning, however.

296 LYME DISEASE

GARY P. WORMSER

DEFINITION

Lyme disease (also known as Lyme borreliosis) is a zoonotic infection that is transmitted by certain *Ixodes* tick species and caused by a group of related spirochetes referred to formally as *Borrelia burgdorferi* sensu lato, or more simply as Lyme borrelia. Lyme disease was first described in 1977 after an investigation of a cluster of cases of arthritis among children living in the area of Lyme, Connecticut. With approximately 475,000 cases estimated to be diagnosed annually,[1] it is the most common vector-borne infection in the United States; Lyme disease is also an infection of public health importance in both Europe and Asia. The most common clinical manifestation is a characteristic skin lesion called erythema migrans. This lesion is a result of inflammation associated with the centrifugal spread of the spirochete within the skin from the site where the tick deposited the microorganism. The spirochete may also spread hematogenously to other skin locations, thereby resulting in secondary erythema migrans skin lesions, or to nonskin sites, such as the joints, nervous system, or heart, thereby leading to a variety of extracutaneous clinical manifestations.

The Pathogen

In the United States, the species of Lyme borrelia that causes the vast majority of human infections is *B. burgdorferi* (also referred to as *B. burgdorferi* sensu stricto). Although *B. burgdorferi* also causes Lyme disease in Europe, collectively other species of Lyme borrelia that can be distinguished genotypically account for the majority of infections there, especially *Borrelia afzelii* and *Borrelia garinii*. The fact that at least six species of Lyme borrelia may cause infection in Europe has created serodiagnostic challenges and accounts for a wider variety of possible clinical manifestations there than in the United States (see later). *B. garinii* appears to be the most neurotropic and *B. burgdorferi* the most arthritogenic among the species of Lyme borrelia.

Lyme borrelia are motile, microaerophilic, spirochetal bacteria with 3 to 10 loose coils arranged in a helical shape. The cells are 10 to 30 µm in length and 0.2 to 0.5 µm in width, and they contain at least seven periplasmic flagella that are responsible for the organism's motility. Borrelia are too thin to be seen by Gram stain, but live organisms can be visualized by dark-field or phase contrast microscopy. In tissues, they can be recognized by light microscopy after application of silver stains or by fluorescent microscopic methods. Lyme borrelia can be grown in vitro in a highly enriched culture medium.

EPIDEMIOLOGY

In the United States, more than 95% of cases of Lyme disease are concentrated in just 14 states: 12 eastern states and 2 in the North Central region.[2] The states with the largest number of cases are Pennsylvania, New York, New Jersey, and Massachusetts. *Ixodes scapularis* (also known as the deer tick or black-legged tick) is the tick vector in these states. *Ixodes pacificus* is the vector for cases that occur in the Northwest region. Lyme disease also occurs in limited areas of Canada. Although Lyme borrelia exist in enzootic cycles in the Southern United States, cases of Lyme disease arising indigenously have not been well documented in states south of North Carolina.

Cases of Lyme disease occur throughout the temperate regions of Europe and are especially common in Scandinavia and countries of Central Europe such as Slovenia, Austria, and Germany.[3] *Ixodes ricinus* transmits the infection in Europe, and *Ixodes persulcatus* is the vector in the Asian region of Russia, China, and Japan.

The principal reservoirs for Lyme borrelia (i.e., source of infection for ticks) in the United States and Eurasia are small mammals such as mice and certain species of birds. Deer play an essential role in the life cycle of the *I. scapularis* tick species but are not a competent reservoir for *B. burgdorferi*.

The likelihood of acquiring Lyme disease is directly related to exposure to environments in which infected ticks are present. Of the three feeding stages in the life cycle of *I. scapularis*, the second or nymphal stage is the most important epidemiologically for transmission of infection to humans. The first or larval stage is uninfected and cannot transmit this infection. Although the third stage (i.e., the adult stage of the tick) is more likely to be infected with *B. burgdorferi* than the nymphal stage is, it is less important in transmission to humans because this stage is present in smaller numbers in the environment and because there is less human activity outdoors during the time periods in the spring and fall when this stage is seeking a blood meal. In addition, adult ticks are larger and their bites cause more skin irritation than bites of nymphal ticks do, thereby increasing the likelihood that they will be noticed and detached by a person who has been bitten. If they are not removed, *Ixodes* ticks will usually feed for at least 3 days (Fig. 296-1). Transmission of *B. burgdorferi* by *I. scapularis* or *I. pacificus* ticks is typically delayed for more than 36 hours from the start of the blood meal, thereby providing the opportunity to prevent infection simply by finding and removing the tick. Transmission of *B. afzelii* by the European tick *I. ricinus* is considerably faster, however, often occurring within the first 24 hours of feeding.

Most cases of erythema migrans in the United States occur during June through August. The age distribution is bimodal, with the highest incidences in children 5 to 15 years old and in adults 45 to 55 years of age, but individuals of all ages are at risk. The reported incidence of Lyme disease in the United States is rising, partially as a result of expansion of the deer population and the spread of infected *I. scapularis* ticks to new geographic areas.

Extracutaneous manifestations are somewhat less likely than erythema migrans to occur during June to August because the time from the tick bite until the onset of these manifestations is longer. Because adult *I. scapularis* ticks may become active on warm days during the winter, cases of erythema migrans may occasionally occur even in the colder months.

PATHOBIOLOGY

B. burgdorferi is deposited by the tick into the skin rather than directly into the blood stream. Hematogenous dissemination seems to be an important mechanism responsible for spread of the spirochete to other sites. Alternatively,

ABSTRACT

Lyme disease is a spirochetal infection that occurs in North America and Eurasia. It is the most common tick-borne disease in North America. Early localized infection after tick bite is manifested by a single erythema migrans skin lesion, which is the most common and most characteristic clinical manifestation of Lyme disease. Early disseminated infection can take the form of Lyme carditis or early neurologic Lyme disease. Late disease is usually characterized by arthritis. Typical erythema migrans can be diagnosed clinically and does not require laboratory testing. For later, non–erythema migrans presentations of Lyme disease, the mainstay of laboratory diagnosis is two-tier serologic testing. The first tier test is a sensitive enzyme-linked immunoabsorbent assay (EIA). If this test is positive or equivocal, most often separate IgM and IgG immunoblots are performed on the original blood sample. With persistent symptoms for more than 4 weeks, the IgG immunoblot should be positive. Oral antibiotic therapy with doxycycline, amoxicillin, or cefuroxime axetil is the preferred treatment for the most frequent clinical manifestation (i.e., erythema migrans).

spread of the spirochete to other sites might occur through tissue planes. The likelihood of entry into the blood stream is affected by the strain of Lyme borrelia causing the infection. Unlike patients who are bacteremic with more conventional pathogens, patients with spirochetemia rarely appear "septic." In one study, only 5% of 93 spirochetemic patients were febrile when the blood culture specimen was obtained, and almost none was found to have leukocytosis. The lack of fever and other clinical signs of sepsis may be due to the absence of lipopolysaccharide within the borrelial cell wall.

B. burgdorferi resides in the midgut of the *Ixodes* tick through attachment of its outer surface protein A (OspA) to the cells lining this site. Genetic studies suggest the nearly complete absence of biosynthetic pathways, thereby making the microorganism dependent on its environment for nutritional requirements. With the onset of the blood meal, the spirochete increases in number and undergoes a sequence of phenotypic changes, including downregulation of OspA expression and upregulation of another outer surface protein, OspC. This set of events releases the spirochete from the midgut and permits migration to the salivary gland. At that site, OspC binds to a salivary protein, Salp15, that is induced during the blood meal in borrelia-infected ticks; this binding protects the spirochete from antibody-mediated killing and aids in transmission to a vertebrate host.

Infection of humans or animals elicits innate and adaptive immune responses,[4] thereby resulting in both macrophage and antibody-mediated killing of the spirochete. The inflammatory response in tissue typically shows an infiltration of lymphocytes, macrophages, and plasma cells, although granulocytes predominate in synovial fluid samples of patients with Lyme arthritis. The potential for persistence of infection despite a robust humoral and cellular immunologic response is, however, typical of infection with Lyme borrelia, as it is with *Treponema pallidum* infection (Chapter 295). The virulence factors responsible for persistence of infection include the spirochete's ability to downregulate expression of certain immunogenic surface-exposed proteins, including OspC, and to alter rapidly and continually by recombination of the antigenic properties of a surface lipoprotein known as variable major protein–like sequence expressed (VlsE). In addition, the spirochete's motility and ability to bind to various components of the extracellular matrix may also contribute to persistence.

All of the objective clinical manifestations of Lyme disease are thought to be due to an inflammatory response to live spirochetes or to their undegraded antigens. Obliterative endarteritis has been seen histologically in synovial tissue, but its importance in pathogenesis is unclear. Lyme borrelia are not known to produce toxins. In humans, the only role so far established for host genetic factors is in the development of antibiotic-refractory Lyme arthritis, also known as post-antibiotic Lyme arthritis, which is seen most often in patients with certain HLA DR alleles, some of which coincide with those associated with rheumatoid arthritis.

CLINICAL MANIFESTATIONS

The clinical manifestations are often categorized as follows:

- Early localized infection, typically manifested by a single erythema migrans (Fig. 296-2) skin lesion, with or without viral infection–like symptoms but without objective extracutaneous manifestations
- Early disseminated infection, usually manifested by multiple erythema migrans skin lesions or by an objective manifestation of early neurologic Lyme disease or Lyme carditis
- Late disease, usually manifested by arthritis but may also include certain rare neurologic manifestations or the skin condition known as acrodermatitis chronica atrophicans (Fig. 296-3).

Children and adults have similar clinical manifestations. In a large European series, erythema migrans by itself was seen in about 90% of cases, arthritis in 5%, early neurologic manifestations in about 3%, borrelial lymphocytoma (see later under "Borrelial Lymphocytoma") in 2%, acrodermatitis chronica atrophicans in 1%, and cardiac manifestations in less than 1%; none of the patients had late neurologic Lyme disease. In a recent case series in the United States, findings have been similar except for the absence of borrelial lymphocytoma and acrodermatitis chronica atrophicans. The much higher prevalence of neurologic, cardiac, or joint manifestations in older studies may have been related to ascertainment bias or to the failure to treat patients with erythema migrans before the development of extracutaneous complications.

Early Localized Infection

Single Erythema Migrans Skin Lesion

Erythema migrans is by far the most common clinical manifestation of Lyme disease. Although the appearance of the skin lesion is often distinctive (see Fig. 296-2), it is not pathognomonic for Lyme disease. Erythema migrans appears 7 to 14 days (range, 3 to 30 days) after tick detachment and is characterized by an expanding, flat to slightly raised, erythematous skin lesion (usually ≥5 cm in diameter) that is round or oval. The bite mark from the preceding tick bite

TABLE 296-1 CLINICAL SYMPTOMS AND SIGNS PRESENT IN AT LEAST 20% OF PATIENTS WITH ERYTHEMA MIGRANS

CHARACTERISTIC	UNITED STATES (95% CI)
Viral infection–like	65% (52-76%)
Fatigue	47% (37-58%)
Headache	36% (27-46%)
Myalgias	35% (26-45%)
Arthralgias	35% (25-46%)
Fever	33% (23-43%)
Stiff neck	31% (21-43%)
Lymphadenopathy	22% (13-33%)
Dysesthesia	20% (12-32%)
	EUROPE (95% CI)
Viral infection–like	37% (27-49%)
Dysesthesia	35% (25-47%)
Headache	20% (14-29%)

CI = confidence interval.

FIGURE 296-4. Borrelial lymphocytoma. A rare cutaneous manifestation of Lyme disease that is seen predominantly outside the United States; it is manifested as a solitary bluish-red swelling most commonly on the earlobe of children and the breast in adults. (Courtesy Dr. Franc Strle.)

can sometimes be identified at or near the center of the lesion and is called a punctum. Approximately 80% of patients in the United States with erythema migrans have just a single skin lesion. Nonspecific viral infection–like symptoms or signs, such as malaise, neck pain, headache, fatigue, migratory arthralgias, or chills and fever, may be present (Table 296-1) but are more common in patients infected with *B. burgdorferi* or *B. garinii* compared with *B. afzelii*. Prominent respiratory or gastrointestinal symptoms are highly atypical for Lyme disease. An acute febrile illness in the absence of a skin lesion or other objective clinical manifestation has been attributed to early Lyme disease, but the possibility of misdiagnosis is greater in this situation because of the potential for false-positive serologic test results.

Erythema migrans skin lesions can vary in appearance. Some (especially lesions of short duration) are nearly uniform in color, whereas others may show central clearing or a target-like appearance. About 5% have a vesicular-pustular center. Erythema migrans on the lower extremities may sometimes be purpuric. Lesions may be scaly when they are long-standing and fading or after topical corticosteroid creams have been applied. The most common locations include the thigh, back, shoulder, and calf. Lesions are often asymptomatic but can be mildly painful or pruritic, and tender regional lymphadenopathy may be present. The majority of U.S. patients with erythema migrans, as for all other clinical manifestations, do not recall a preceding tick bite.

Borrelial Lymphocytoma

Borrelial lymphocytoma, which is a rare cutaneous manifestation of Lyme disease, almost never occurs in the United States. It often is manifested at or near a preceding tick bite as a solitary bluish-red swelling with a diameter of up to a few centimeters. The most common locations are the earlobe in children and the breast in adults (Fig. 296-4). Histologic examination shows a dense infiltration of the cutis and subcutis by predominantly polyclonal B lymphocytes, frequently with germinal center formation. Histologic evaluation may be necessary to exclude malignant disease for patients with suspected borrelial lymphocytoma at a location other than the earlobe.

Early Disseminated Infection

Multiple Erythema Migrans Skin Lesions

In the United States, approximately 20% of patients with erythema migrans have multiple skin lesions at the time of presentation. Secondary erythema migrans skin lesions can be smaller than 5 cm, do not have a punctum, and are usually not tender or pruritic; they arise from hematogenous dissemination to the skin rather than from additional tick bites.

Early Neurologic Lyme Disease

Within weeks to several months after infection, patients may develop neurologic manifestations, the most common of which are cranial neuropathy (particularly peripheral seventh nerve palsy that may be bilateral), lymphocytic meningitis, and sensory (often painful) radiculopathy.[5,6] Less common manifestations include mononeuritis multiplex (multifocal involvement of anatomically unrelated nerves) and brachial or lumbosacral plexopathies. A pseudotumor cerebri–like picture has been reported occasionally in children. The presence of a concomitant erythema migrans lesion or the patient's recollection of a recent lesion consistent with erythema migrans may be helpful diagnostically.

Cardiac Lyme Disease

Weeks to months after infection, patients may develop cardiac manifestations of Lyme disease, most often fluctuating degrees of atrioventricular heart block or other manifestations of a myopericarditis (Chapter 47), which may cause the patient to complain of lightheadedness, palpitations, dyspnea, chest pain, or syncope.[7] Heart block is typically at or above the atrioventricular node. Erythema migrans is often, but not invariably, present concurrently. Valvular dysfunction is not known to occur, and chronic cardiomyopathy has been reported only rarely in Europe.

Late Lyme Disease

Lyme Arthritis

If patients with erythema migrans in the United States are not treated with antibiotics, approximately 60% will develop a monoarticular or oligoarticular arthritis at a mean of 6 months after disease onset (range, 4 days to as long as 2 years). In untreated patients, Lyme arthritis is characterized by intermittent attacks of synovitis that persist for a few weeks to several months. One or two joints are involved at a time. Primarily large joints are affected,[8] but the temporomandibular joint, small joints, and periarticular sites may be involved. The most commonly involved joint is the knee. Baker cysts (Chapter 242) may form and rupture. Joint swelling is often pronounced, but pain is usually relatively modest. Children in particular may have concomitant fever, but adults are often minimally symptomatic aside from the arthritis.

In about 10% of adult patients with Lyme arthritis in the United States, involvement of a large joint (almost always the knee) may persist despite appropriate antibiotic treatment.[9] Erosion of cartilage or bone may develop in such cases.

Late Neurologic Lyme Disease

After months to years of infection, the late neurologic manifestation, encephalomyelitis, may develop. In untreated patients, encephalomyelitis has been monophasic and slowly progressive, mainly involving white matter. It is the

most severe neurologic manifestation and, although infrequent, is probably more common in Europe than in the United States.

Acrodermatitis Chronica Atrophicans

Acrodermatitis chronica atrophicans (Fig. 296-3), which is a late skin manifestation of Lyme disease, is most commonly seen in women older than age 40 years. Although presumably any of the species of Lyme borrelia may cause acrodermatitis chronica atrophicans, by far the most common etiologic agent is *B. afzelii*. Therefore, this manifestation is rarely seen in the United States.

This skin lesion develops insidiously several years after initial infection, usually on the extensor surfaces of the hands and feet. Early lesions are characterized by a slight bluish-red discoloration and doughy swelling. Histologic examination shows lymphocytes and plasma cells in the skin and sometimes in the subcutis, with or without atrophy. Initially unilateral, the lesion may later become bilateral. Over time, the edema resolves, but skin atrophy may develop. Nodules may develop over bone prominences. About two thirds of patients have an associated peripheral neuropathy, primarily of the affected extremity, usually manifested as local sensory loss.

DIAGNOSIS

The diagnosis of Lyme disease requires clinical suspicion and often requires targeted laboratory testing (Table 296-2). In the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) era, diagnosis can be delayed, either because symptoms are misattributed or patients delay seeking medical care.[10,11]

Erythema migrans skin lesions may go unnoticed by the patient because of the absence of prominent local symptoms and occurrence on parts of the body that are difficult for the patient to visualize. Therefore, a complete skin examination should be performed for any patient thought to have early localized or disseminated Lyme disease. Erythema migrans, which is the only clinical manifestation sufficiently distinctive to allow a clinical diagnosis in the absence of a supporting laboratory test, is diagnosed on the basis of recognition of the characteristic appearance of the skin lesion in persons who live in or have recently traveled to areas endemic for Lyme disease.

For non–erythema migrans presentations of Lyme disease, the mainstay of laboratory diagnosis is two-tier serologic testing in which the first-tier test is usually a sensitive enzyme-linked immunosorbent assay (EIA).[12,13] If the EIA result is positive or equivocal, separate IgM and IgG immunoblots are performed on the original serum sample. If symptoms have persisted for at least 4 weeks, then specifically the IgG immunoblot should be positive for the results to be interpreted as evidence of seropositivity. An alternative two-tier testing strategy is to use a different EIA as the second-tier test. Untreated patients who remain seronegative for 6 to 8 weeks are unlikely to have Lyme disease, and other possible diagnoses should be pursued.

TABLE 296-2 DIAGNOSIS OF LYME DISEASE

DIAGNOSTIC MODALITY	APPLICATION	COMMENT
Visual inspection	Erythema migrans	Usually seronegative at time of presentation
Two-tier serology* with a positive IgM and/or IgG immunoblot	Lyme carditis	Look for concomitant erythema migrans
	Early neurologic Lyme disease	Look for concomitant erythema migrans; intrathecal antibody may be detectable before serum antibody in Europe; PCR sometimes positive in CSF
	Borrelial lymphocytoma	Biopsy may be needed to exclude a malignant neoplasm
Two-tier serology with a positive IgG immunoblot	Lyme arthritis	PCR often positive on synovial fluid
	Late neurologic Lyme disease	Intrathecal antibody positivity expected in Lyme encephalomyelitis
	Acrodermatitis chronica atrophicans	

*Two-tier serologic testing consists of a sensitive enzyme immunoassay (EIA) as the first-tier test, followed by separate IgM and IgG blot testing if the EIA is reactive. An alternative two-tier testing strategy is to use another EIA as the second-tier test (see text).
CSF = cerebrospinal fluid; Ig = immunoglobulin; PCR = polymerase chain reaction.

Omitting the first-tier EIA or interpreting the immunoblot with alternative criteria that are not evidence based will potentially decrease the specificity of testing and is not recommended. False-positive results on the IgM immunoblot may be due to cross-reactive antibodies that arise from polyclonal B-cell stimulation. Probably the most common cause of false-positive results, however, is the overreading of nonspecific weak bands. Background rates of seropositivity, which may exceed 4% in highly endemic areas of the United States and be even higher in Europe, may also confound the interpretation of seroreactivity. Therefore, a positive serologic test result does not mean that the patient necessarily has active Lyme disease. The positive predictive value is most informative when the pretest probability based on the clinical features is at least 20%.

Cerebrospinal fluid (CSF) testing may be performed in patients with suspected Lyme neuroborreliosis, including testing for intrathecal antibody production.[14] In encephalomyelitis, CSF examination typically shows a >90% lymphocytic pleocytosis, a moderately elevated protein level, and a normal glucose level, with evidence of intrathecal production of antibody to borrelia. Magnetic resonance imaging of the affected part of the brain or spinal cord can demonstrate areas of inflammation, typically with increased signal on T2 and fluid attenuation inversion recovery imaging and enhancement after administration of contrast material. Of note, positive test results for intrathecal antibody may persist for long periods despite successful antibiotic treatment. The sensitivity of polymerase chain reaction testing (PCR) in CSF is too low for it to be a useful diagnostic test.

Examination of the synovial fluid may be performed in patients with suspected Lyme arthritis. Synovial fluid in Lyme arthritis typically shows approximately 25,000 white cells/μL (range, 500 to 110,000/μL) with a polymorphonuclear predominance. PCR testing for detection of borrelial DNA is positive on synovial fluid specimens in up to approximately 80% of untreated patients with Lyme arthritis, and a positive result lends support for this diagnosis in a patient who is IgG seropositive.

General Laboratory Testing

Blood counts are usually normal in Lyme disease, unless coinfection with *Anaplasma phagocytophilum* (ehrlichiosis; Chapter 302), *Babesia microti* (Chapter 324), or a tick-borne encephalitis virus (Chapter 352) is present (see later). Lymphopenia, however, may be found in the absence of a recognized coinfection. In patients with erythema migrans, mild abnormalities of liver function tests (particularly elevations of aspartate and alanine aminotransferase levels) can be seen in approximately 35% of patients. The erythrocyte sedimentation rate may be modestly elevated in all stages of Lyme disease, but values greater than 80 mm/hour are distinctly uncommon.

Differential Diagnosis

Erythema Migrans

Tick-bite hypersensitivity reactions can be mistaken for erythema migrans, but these reactions occur within 48 hours of a tick bite, are usually pruritic, and tend to wane within a few days. In contrast, erythema migrans skin lesions in untreated patients will persist for a median of approximately 4 weeks in the United States and even longer in Europe. Bacterial cellulitis (see Fig. 408-2) rarely occurs at the most frequent skin sites for erythema migrans and would not be expected to demonstrate central clearing or a target-like appearance. Erythema migrans, unlike erythema multiforme (see Fig. 406-16), does not involve the mucous membranes, palms, or soles. Southern tick-associated rash illness (STARI) is the most likely diagnosis in patients with erythema migrans–like skin lesions who were bitten by an *Amblyomma americanum* tick or developed this lesion in the Southern United States. Other considerations in the differential diagnosis of erythema migrans that usually can be readily distinguished include tinea versicolor (often pruritic with a thin, raised, scaly border; see Fig. 405-29), nummular eczema (symmetrical pruritic lesions with a tendency to scale and crust; see Fig. 405-2), granuloma annulare (acral location, especially on the dorsum of hands and feet, relatively fixed in size and <5 cm in diameter), contact dermatitis (pruritic with streaking along the area of contact and a vesicular component; see Table 403-5), urticaria (raised, pruritic, and usually <5 cm in diameter; see Fig. 407-1), fixed drug eruption (usually on genitals, hands, feet, or face and fixed in size; see Fig. 407-3), pityriasis rosea (multiple moderately pruritic lesions with peripheral scale and relatively fixed in size; see Fig. 405-18), and a spider bite (often very painful and necrotic with a central eschar; Chapter 98).

Extracutaneous Lyme Disease

Included in the differential diagnosis of early neurologic Lyme disease is Bell palsy (Chapter 388). Even in highly endemic areas of the United States, other causes of

seventh nerve palsy outnumber Lyme disease by a margin of 3 : 1. Viral meningitis (Chapter 381) and mechanical radiculopathy (Chapter 369) can also potentially be confused with manifestations of early neurologic Lyme disease. Viral or other causes of myopericarditis (Chapter 47) may resemble cardiac Lyme disease. Many causes of synovitis (Chapters 236 and 254) might be considered in the differential diagnosis of Lyme arthritis, but the pattern of joint involvement, such as symmetrical small joint involvement in rheumatoid arthritis (Chapter 243), is often distinctly different from that found in Lyme arthritis. Lyme encephalomyelitis may occasionally be confused clinically with a first episode of relapsing-remitting multiple sclerosis or primary progressive multiple sclerosis (Chapter 380). Testing for borrelial antibody in serum (and CSF for the last condition) usually suffices to differentiate these conditions from Lyme disease.

TREATMENT

Although most manifestations of Lyme disease will resolve spontaneously without treatment, antibiotic therapy may hasten resolution and prevent progression. Lyme borrelia are highly susceptible to tetracyclines, most penicillins, and many second- and third-generation cephalosporins but are resistant to certain fluoroquinolones, rifampin, and first-generation cephalosporins.

Erythema Migrans

For erythema migrans, oral doxycycline, amoxicillin, and cefuroxime axetil are each highly effective[A1] and are the preferred agents (Table 296-3).[15] Macrolides such as azithromycin are somewhat less effective and are not recommended as first-line therapy.

Doxycycline is the only first-line agent proven to be effective against *A. phagocytophilum* coinfection. Doxycycline, however, may cause photosensitivity, which is a concern because early Lyme disease occurs most commonly during the summer months. When erythema migrans cannot be reliably distinguished from community-acquired bacterial cellulitis, cefuroxime axetil is preferred because it is generally effective against both types of infection.

Within 24 hours of initiation of antimicrobial therapy, up to 15% of patients treated for erythema migrans will experience a Jarisch-Herxheimer–like reaction characterized by an increase in the size or intensity of erythema in the skin lesion and more intense viral infection–like systemic symptoms. Fever, if present, should resolve within 48 hours and the skin lesion itself within 7 to 14 days. Other symptoms, such as fatigue or arthralgia, tend to improve but not invariably to resolve within this time frame, lasting for more than 3 months in one quarter of patients. Oral antibiotic therapy is also used as first-line treatment for the other cutaneous manifestations of Lyme disease.

Neurologic Lyme Disease

For early neurologic Lyme disease, especially uncomplicated seventh nerve palsy, meningitis, and radiculitis, oral doxycycline is recommended as a first-line therapy.[A2–A4] Amoxicillin is an alternative for patients with uncomplicated seventh nerve palsy, but seventh nerve palsy typically resolves at the same rate with or without antibiotic treatment. Therefore, the primary reason to treat such patients is to prevent the subsequent development of later complications, particularly Lyme arthritis.

Parenteral antibiotic therapy is recommended to treat patients with late neurologic Lyme disease. The preferred parenteral agent is ceftriaxone, which is highly active, crosses the blood-brain barrier, and has a long serum half-life that allows once-daily administration (see Table 296-3). Alternative parenteral options are cefotaxime and intravenous penicillin.

The presence of either papilledema or sixth cranial nerve palsy may indicate the presence of increased intracranial pressure in patients with neurologic Lyme disease. The elevated pressure will typically fall in response to antibiotic therapy, but other measures conventionally used to lower pressure may need to be considered in individual cases.

Lyme Myocarditis

Symptomatic patients with cardiac Lyme disease and those with high-grade first-degree atrioventricular heart block (PR interval of ≥300 msec) and second- or third-degree block should be hospitalized and closely monitored (Chapter 51). Temporary cardiac pacing may be required. In treated patients, complete heart block generally resolves within 1 week, and lesser conduction disturbances resolve within 6 weeks.

Lyme Arthritis

The treatment of Lyme arthritis typically begins with a 28-day course of an oral antibiotic. Patients whose arthritis is improved but not resolved after an initial course of oral therapy may be re-treated with a second course of oral antibiotics, with parenteral antibiotic therapy reserved for those without any significant clinical response.

Lyme in Pregnancy

Pregnant patients with Lyme disease are generally treated similarly to nonpregnant patients except that doxycycline is relatively contraindicated. No data convincingly support a congenital Lyme disease syndrome.

TABLE 296-3 RECOMMENDED THERAPY FOR ADULT PATIENTS WITH LYME DISEASE*

THERAPY	MANIFESTATION	DURATION
Doxycycline 100 mg PO bid *or*	Erythema migrans	10-14 days[‡]
	Borrelial lymphocytoma	14 days
Amoxicillin 500 mg PO tid *or*	Acrodermatitis chronica atrophicans	21-28 days
	Lyme arthritis	28 days
Cefuroxime axetil 500 mg PO bid	Lyme carditis—mild	14-21 days
	Cranial neuropathy	14-21 days[§]
Doxycycline 200 mg PO daily or 100 mg PO bid	Lyme meningitis or radiculopathy	14-21 days
Ceftriaxone 2 g IV daily[†]	Lyme arthritis that failed to respond to oral therapy	14-28 days
	Late neurologic Lyme disease	14-28 days
	Lyme carditis requiring hospitalization	14-21 days
	Lyme meningitis or radiculopathy requiring hospitalization	14-21 days
Azithromycin 500 mg PO daily	Erythema migrans in a patient intolerant of doxycycline and β-lactam antibiotics	7 days

*Regardless of the clinical manifestations of Lyme disease, complete response to treatment may be delayed beyond the treatment duration. Relapse may occur with any of these regimens; patients with objective signs of relapse may need another course of treatment.

[†]Cefotaxime 2 g IV q8h or IV penicillin G 18-24 million U per day IV (total daily dose is divided into an every-4-hour regimen) are alternative choices for patients with normal renal function.

[‡]10 days for doxycycline; 14 days for amoxicillin or cefuroxime axetil.

[§]Although any one of first-line oral antibiotics appears to be effective in patients with cranial neuropathy, there is only limited experience in patients with a cranial neuropathy other than seventh nerve palsy or with agents other than doxycycline.

bid = twice daily; IV = intravenous; PO = oral; tid = 3 times daily.

Modified from Lantos PM, Rumbaugh J, Bockenstedt LK, et al. Clinical practice guidelines by the Infectious Diseases Society of America, American Academy of Neurology, and American College of Rheumatology: 2020 guidelines for the prevention, diagnosis, and treatment of Lyme disease. *Clin Infect Dis*. 2021; 72:e1-e48.

Coinfections

Ixodes ticks may be coinfected with and transmit Lyme borrelia along with other pathogens, such as *A. phagocytophilum*, *B. microti* (the primary cause of babesiosis), and a tick-borne encephalitis virus. The likelihood of coinfection is dependent on the particular species of *Ixodes* tick and on the geographic area. Thus, bites from *I. scapularis* ticks in certain areas may lead to the development of Lyme disease, human granulocytic anaplasmosis (Chapter 302), or babesiosis (Chapter 324) as a single infection or, less frequently, as a coinfection. In addition, this tick species can potentially transmit the deer tick virus subtype of the Powassan virus, an *Ehrlichia* species referred to as *Ehrlichia muris eauclarensis*, and *Borrelia miyamotoi*. In Europe, the most common coinfection is Lyme disease with tick-borne encephalitis virus infection.

Coinfection should be considered in patients from geographic areas endemic for these pathogens who present with more severe initial symptoms than are commonly observed with Lyme disease alone: high-grade fever for more than 48 hours despite antibiotic therapy appropriate for Lyme disease, recurrent fever, or unexplained leukopenia, thrombocytopenia, or anemia. Coinfection might also be considered when the erythema migrans skin lesion has resolved, but the viral infection–like symptoms either did not improve or worsened.

Reinfection

Patients who are treated for early Lyme disease do not appear to develop an immunologic response that is adequate to protect against reinfection with a different strain of *B. burgdorferi*. Therefore, patients with erythema migrans may become reinfected at a different skin site if bitten by another infected tick. Reinfection has been well documented only in patients who were treated for early infection (nearly always erythema migrans) and not after late manifestations of Lyme disease, such as Lyme arthritis. Clinical manifestations of reinfection appear to be similar to those of the primary infection. Treatment is as for the initial infection.

PREVENTION

Lyme disease can be prevented by avoiding tick-infested environments, as well as by covering bare skin and using tick repellents on skin and clothing when in such environments.[16] The tick density around individual residences can be reduced by removing leaf litter, placing wood chips where lawns abut forests, and constructing fences to keep out deer. Applying acaricides to residential

property can reduce the number of ticks but not necessarily to a level that will reduce household tick exposure or human diseases.[A5] Bathing within 2 hours of tick exposure has been shown to decrease the risk of Lyme disease. For outdoor workers with high exposure to potentially infected ticks, long-lasting permethrin-impregnated clothing can reduce tick bites by about 60%.[A6]

Daily inspections of the entire skin surface (including scalp) to remove attached ticks is recommended because of the grace period between the time of tick attachment and transmission of *B. burgdorferi*. Removal is accomplished by grasping the tick as close to its mouth parts as possible with a forceps (or tweezers) and then gently pulling it out. Clinical studies have demonstrated that without any other intervention, more than 96% of patients who find and remove an attached *I. scapularis* tick will remain free of Lyme disease, even in highly endemic geographic regions. If the tick is not found or removed, the probability of infection approaches the infection rate in the regional tick population (typically >20% of nymphal stage *I. scapularis* ticks are infected in highly endemic areas of the Northeast and Midwest United States).

A single 200-mg dose of doxycycline within 72 hours of tick removal is about 70 to 90% effective in preventing erythema migrans at the tick bite site.[A7,A8] This chemoprophylaxis should be considered for persons who are in highly endemic areas and who are known to have been bitten by a nymphal or adult *I. scapularis* tick that was estimated to have been attached for at least 36 hours. Given the uncertain efficacy of a short course of amoxicillin in this situation, observation rather than chemoprophylaxis has been recommended for individuals for whom doxycycline is contraindicated. Topical azithromycin provides no prevention effect.[A9] No vaccine is currently available to prevent Lyme disease in humans.

PROGNOSIS

The outcome of treatment in most patients with erythema migrans is excellent.[17] Serologic testing is not indicated in routine follow-up of patients after treatment because either IgM or IgG borrelial antibodies may persist for many years in successfully treated patients.

Chronic Lyme Arthritis

Approximately 10% of adult patients with Lyme arthritis in the United States do not respond clinically to antibiotic therapy and are said to have antibiotic-refractory Lyme arthritis, also known as post-antibiotic Lyme arthritis, which is defined as persistent synovitis for at least 2 months after completion of a course of intravenous ceftriaxone (or 1 month after completion of two 4-week courses of an oral antibiotic). Because these patients are no longer believed to be actively infected, they are customarily treated with nonsteroidal anti-inflammatory agents, intra-articular injections of corticosteroids, or a 6- to 12-month course of disease-modifying antirheumatic drugs (see Chapter 243). Arthroscopic synovectomy has also been used successfully for patients with this condition.

Cardiac Lyme disease typically resolves completely. For neurologic disease, treatment prevents progression but does not always completely resolve neurologic dysfunction.

Post–Lyme Disease and Syndrome

When questioned at 6 months or more after treatment of erythema migrans, approximately 10% of patients will report purely subjective symptoms such as fatigue or musculoskeletal pains. These subjective symptoms are typically mild and may wax and wane in intensity. Patients who have them are referred to as having post–Lyme disease symptoms or syndrome, depending on the symptom duration and severity. The cause of these symptoms is currently unknown. Careful microbiologic evaluations have failed to find evidence of either persistent *B. burgdorferi* infection or a coinfection with a second *Ixodes*-transmitted pathogen. In patients with persistent symptoms attributed to Lyme disease, retreatment with antibiotics, irrespective of duration, has provided either no measurable benefit or a benefit so modest or ambiguous that it was outweighed by the risks associated with the antibiotic therapy.[A10] Therefore, only symptomatic treatment is recommended for such patients.[18]

The term chronic Lyme disease is poorly defined but widely used. Most often, chronic Lyme disease is used as a diagnosis for patients with persistent pain, neurocognitive complaints, or fatigue, without objective clinical or serologic evidence of past or present *B. burgdorferi* infection. In this usage, the term is a misnomer and treatment for Lyme disease is not indicated.

RELAPSING FEVER AND OTHER *BORRELIA* INFECTIONS

WILLIAM A. PETRI, JR.

DEFINITION

Relapsing fever is a spirochetal infection with bacteria of the genus *Borrelia*. The two modes of transmission are epidemic louse-borne and endemic tick-borne relapsing fever.[1] Disease is characterized by recurrent bouts of fever and spirochetemia separated by short fever-free periods.

The Pathogen

Members of the genus *Borrelia* are motile spirochetes that measure 0.5 µm in diameter and 5 to 40 µm in length. The spirochetes are aerophilic and require long-chain fatty acids for growth. Louse-borne relapsing fever is caused by *Borrelia recurrentis*. Tick-borne relapsing fever organisms, which are named after their tick vector, include the closely related species *Borrelia duttonii* (Old World); *Borrelia hermsii, Borrelia turicatae*, and *Borrelia parkeri* (North America); and *Borrelia miyamotoi* (Old and New World).[2]

EPIDEMIOLOGY

Louse-borne epidemic relapsing fever, which is caused by *B. recurrentis*, is carried from person to person by the human body louse (*Pediculus humanus*). There is no animal reservoir. The spirochete lives in the louse hemolymph; infection is transmitted to humans when the louse is crushed on human skin and infective spirochetes penetrate the skin or mucous membranes. Epidemics have occurred during famines and wars, when breakdown in sanitation favors the transmission of body lice. Louse-borne disease remains endemic in Central and East Africa (Ethiopia, Somalia, Chad, and the Sudan)[3] and in the South American Andes (Bolivia and Peru). It is also seen in Eastern Europe[4] and in recent refugees to Western Europe.

Tick-borne endemic relapsing fever, which occurs throughout the world, is transmitted to humans by *Ornithodoros* soft ticks. The ticks become infected by feeding on wild rodents (including mice, rats, squirrels, and chipmunks), which serve as natural reservoirs for the organisms. In the United States, relapsing fever is limited to humid mountainous areas of the West at altitudes of 1500 to 8000 feet, where the tick vector *Ornithodoros hermsii* resides in forests of ponderosa pine and Douglas fir trees. A key diagnostic clue has been a history of sleeping in rodent-infested cabins in western U.S. national parks.

property can reduce the number of ticks but not necessarily to a level that will reduce household tick exposure or human diseases.[A5] Bathing within 2 hours of tick exposure has been shown to decrease the risk of Lyme disease. For outdoor workers with high exposure to potentially infected ticks, long-lasting permethrin-impregnated clothing can reduce tick bites by about 60%.[A6]

Daily inspections of the entire skin surface (including scalp) to remove attached ticks is recommended because of the grace period between the time of tick attachment and transmission of *B. burgdorferi*. Removal is accomplished by grasping the tick as close to its mouth parts as possible with a forceps (or tweezers) and then gently pulling it out. Clinical studies have demonstrated that without any other intervention, more than 96% of patients who find and remove an attached *I. scapularis* tick will remain free of Lyme disease, even in highly endemic geographic regions. If the tick is not found or removed, the probability of infection approaches the infection rate in the regional tick population (typically >20% of nymphal stage *I. scapularis* ticks are infected in highly endemic areas of the Northeast and Midwest United States).

A single 200-mg dose of doxycycline within 72 hours of tick removal is about 70 to 90% effective in preventing erythema migrans at the tick bite site.[A7,A8] This chemoprophylaxis should be considered for persons who are in highly endemic areas and who are known to have been bitten by a nymphal or adult *I. scapularis* tick that was estimated to have been attached for at least 36 hours. Given the uncertain efficacy of a short course of amoxicillin in this situation, observation rather than chemoprophylaxis has been recommended for individuals for whom doxycycline is contraindicated. Topical azithromycin provides no prevention effect.[A9] No vaccine is currently available to prevent Lyme disease in humans.

PROGNOSIS

The outcome of treatment in most patients with erythema migrans is excellent.[17] Serologic testing is not indicated in routine follow-up of patients after treatment because either IgM or IgG borrelial antibodies may persist for many years in successfully treated patients.

Chronic Lyme Arthritis

Approximately 10% of adult patients with Lyme arthritis in the United States do not respond clinically to antibiotic therapy and are said to have antibiotic-refractory Lyme arthritis, also known as post-antibiotic Lyme arthritis, which is defined as persistent synovitis for at least 2 months after completion of a course of intravenous ceftriaxone (or 1 month after completion of two 4-week courses of an oral antibiotic). Because these patients are no longer believed to be actively infected, they are customarily treated with nonsteroidal anti-inflammatory agents, intra-articular injections of corticosteroids, or a 6- to 12-month course of disease-modifying antirheumatic drugs (see Chapter 243). Arthroscopic synovectomy has also been used successfully for patients with this condition.

Cardiac Lyme disease typically resolves completely. For neurologic disease, treatment prevents progression but does not always completely resolve neurologic dysfunction.

Post–Lyme Disease and Syndrome

When questioned at 6 months or more after treatment of erythema migrans, approximately 10% of patients will report purely subjective symptoms such as fatigue or musculoskeletal pains. These subjective symptoms are typically mild and may wax and wane in intensity. Patients who have them are referred to as having post–Lyme disease symptoms or syndrome, depending on the symptom duration and severity. The cause of these symptoms is currently unknown. Careful microbiologic evaluations have failed to find evidence of either persistent *B. burgdorferi* infection or a coinfection with a second *Ixodes*-transmitted pathogen. In patients with persistent symptoms attributed to Lyme disease, retreatment with antibiotics, irrespective of duration, has provided either no measurable benefit or a benefit so modest or ambiguous that it was outweighed by the risks associated with the antibiotic therapy.[A10] Therefore, only symptomatic treatment is recommended for such patients.[18]

The term chronic Lyme disease is poorly defined but widely used. Most often, chronic Lyme disease is used as a diagnosis for patients with persistent pain, neurocognitive complaints, or fatigue, without objective clinical or serologic evidence of past or present *B. burgdorferi* infection. In this usage, the term is a misnomer and treatment for Lyme disease is not indicated.

RELAPSING FEVER AND OTHER *BORRELIA* INFECTIONS

WILLIAM A. PETRI, JR.

DEFINITION

Relapsing fever is a spirochetal infection with bacteria of the genus *Borrelia*. The two modes of transmission are epidemic louse-borne and endemic tick-borne relapsing fever.[1] Disease is characterized by recurrent bouts of fever and spirochetemia separated by short fever-free periods.

The Pathogen

Members of the genus *Borrelia* are motile spirochetes that measure 0.5 µm in diameter and 5 to 40 µm in length. The spirochetes are aerophilic and require long-chain fatty acids for growth. Louse-borne relapsing fever is caused by *Borrelia recurrentis*. Tick-borne relapsing fever organisms, which are named after their tick vector, include the closely related species *Borrelia duttonii* (Old World); *Borrelia hermsii, Borrelia turicatae*, and *Borrelia parkeri* (North America); and *Borrelia miyamotoi* (Old and New World).[2]

EPIDEMIOLOGY

Louse-borne epidemic relapsing fever, which is caused by *B. recurrentis*, is carried from person to person by the human body louse (*Pediculus humanus*). There is no animal reservoir. The spirochete lives in the louse hemolymph; infection is transmitted to humans when the louse is crushed on human skin and infective spirochetes penetrate the skin or mucous membranes. Epidemics have occurred during famines and wars, when breakdown in sanitation favors the transmission of body lice. Louse-borne disease remains endemic in Central and East Africa (Ethiopia, Somalia, Chad, and the Sudan)[3] and in the South American Andes (Bolivia and Peru). It is also seen in Eastern Europe[4] and in recent refugees to Western Europe.

Tick-borne endemic relapsing fever, which occurs throughout the world, is transmitted to humans by *Ornithodoros* soft ticks. The ticks become infected by feeding on wild rodents (including mice, rats, squirrels, and chipmunks), which serve as natural reservoirs for the organisms. In the United States, relapsing fever is limited to humid mountainous areas of the West at altitudes of 1500 to 8000 feet, where the tick vector *Ornithodoros hermsii* resides in forests of ponderosa pine and Douglas fir trees. A key diagnostic clue has been a history of sleeping in rodent-infested cabins in western U.S. national parks.

ABSTRACT

Relapsing fever is a spirochetal infection with bacteria of the genus *Borrelia*. There are two modes of transmission: epidemic louse-borne and endemic tick-borne relapsing fever. Disease is characterized by recurrent bouts of fever and spirochetemia separated by short fever-free periods. An abrupt onset of fever (temperature >39° C in most patients), headache, myalgia, and shaking chills characterizes the onset of illness. Signs include fever, tachycardia, lethargy, or confusion; conjunctival injection; and epistaxis. Hepatosplenomegaly, jaundice, and often a truncal petechial rash are common signs in louse-borne relapsing fever. Neurologic findings may occur, including meningitis, meningoencephalitis, and facial palsy, although these entities are more common with tick-borne relapsing fever. Elevated liver enzyme levels, neutropenia, and thrombocytopenia are common. The diagnosis should be considered in patients with fever who are in or traveled from the mountainous and high-elevation areas of the western United States. Because the number of organisms in blood is extremely high, the diagnosis is most often made by direct visualization on a blood smear, although polymerase chain reaction testing is more sensitive. Tetracycline, doxycycline, and erythromycin are all effective antibiotics.

In Tanzania, where house infestation with *Ornithodoros* tick vectors can be very high, relapsing fever can be identified in about 10% of children seen at a clinic with fever. By comparison, the prevalence of antibodies to *Borrelia miyamotoi* is nearly 50%, as high as for *Borrelia burgdorferi* (Chapter 296), in the northeastern United States.

PATHOBIOLOGY

Borrelia infection begins in the skin at the site of the louse or tick bite and is followed by rapid dissemination of the spirochetes through the blood stream. The spirochete burden in blood positively correlates with the severity of symptoms. Clearance of spirochetes from blood is associated with the production of serotype-specific immune sera; anti-*Borrelia* antibodies are the major mechanism of immune clearance of infection.

Relapses are associated with cyclic antigenic variation in the variable major proteins, which are the abundant outer membrane proteins of the spirochete and which carry the serotype-specific epitopes.[5] Antigenic variation is the consequence of recombination events that occur among variable major protein genes at silent and expression sites on linear plasmids. A single *B. hermsii* bacterium may produce as many as 40 distinct serotypes. Because spirochetes undergo one or several antigenic phases during infection, no specific or standard procedure has been developed for routine serodiagnosis of relapsing fever.

CLINICAL MANIFESTATIONS

An abrupt onset of fever (temperature >39° C in most patients), headache, myalgia, and shaking chills characterizes the onset of illness in louse and tick-borne disease. Cough, nausea, vomiting, and fatigue are less frequent complaints. Additional signs include tachycardia, lethargy, confusion, conjunctival injection, and epistaxis.[6] Hepatosplenomegaly, jaundice, and often a truncal petechial rash are common signs in louse-borne relapsing fever. Neurologic findings may include meningitis, meningoencephalitis, and facial palsy, although these manifestations are more common with tick-borne relapsing fever.

Untreated louse-borne disease persists 6 days, and relapses occur once in untreated patients after an afebrile period of 9 days and then do not recur. The initial illness of tick-borne relapsing fever persists for about 4 days without antibiotic treatment, with an average of two relapses (each after an average 10-day intervening afebrile period) before the diagnosis is made; relapses eventually no longer recur even in untreated patients.[7]

B. miyamotoi presents with high fever, chills, marked headache, and myalgia or arthralgia. Elevated liver enzyme levels, neutropenia, and thrombocytopenia are common.

Relapsing fever in pregnancy can cause placental damage and intrauterine growth retardation, with miscarriage in a third of patients. Neonatal infection by both the tick- and louse-borne forms is accompanied by jaundice, hepatosplenomegaly, and often sepsis and hemorrhage. Fever and hepatosplenomegaly are also common signs in children. It has been also recognized in immunocompromised patients.

DIAGNOSIS

In the United States, the diagnosis should be considered in patients who have fever and who are returning from a stay in the mountainous and high-elevation areas of the Western United States.[8,9] Only a few patients will remember tick exposure because *O. hermsii* is a night feeder, has a painless bite, and remains attached for only 15 minutes. Internationally, relapsing fever can occur sporadically or among travelers wherever dwellings are infected with *Ornithodoros* ticks, as well as in epidemics with louse-borne disease.[10]

Polymerase chain reaction testing is highly sensitive and specific.[11] The number of organisms in blood is extremely high, and spirochetes can be demonstrated in a Wright-stained peripheral blood smear taken during febrile episodes in about 70% of patients (Fig. 297-1). Additional sensitivity may be gained by examination of a buffy coat preparation of peripheral blood. Because of their characteristic locomotion, spirochetes can be readily detected by direct visualization of thick blood films under low-power microscopy. The white blood cell count is generally normal, but platelet counts of less than 50,000/μL occur in up to 90% of cases of louse-borne disease. Prothrombin and activated partial thromboplastin times are often prolonged. In louse-borne disease, elevations in liver function test results (serum aminotransferase and bilirubin levels) and blood urea nitrogen are common. Urinalysis may reveal proteinuria and microscopic hematuria. Examination of cerebrospinal fluid may show a lymphocytic pleocytosis, and spirochetes may be directly visualized.

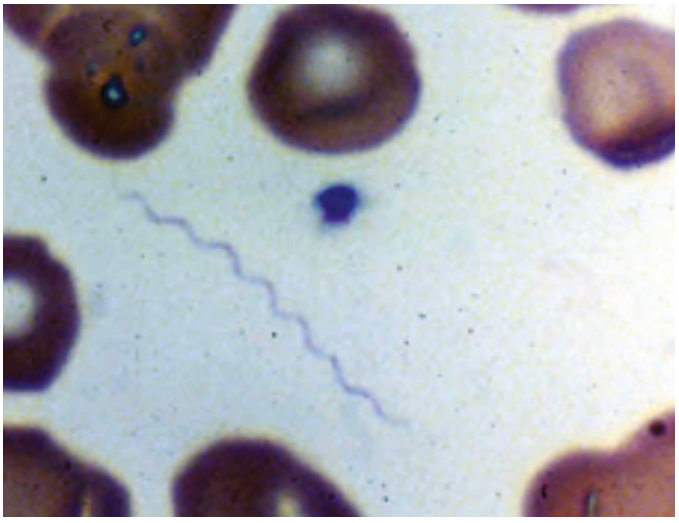

FIGURE 297-1. A single spirochete is seen in a Wright-stained thin blood smear from a patient with relapsing fever.

TREATMENT

Borrelia is generally quite sensitive to antibiotics. For louse-borne disease, options include oral doxycycline (100 mg twice daily for 7 days), tetracycline (500 mg four times daily for 7 days), erythromycin (500 mg four times daily for 10 days), or intravenous ceftriaxone (2 g twice daily for 10 to 14 days). For tick-borne relapsing infection, treatment should extend for 7 days to reduce the risk for persistent infection. Tetracycline should not be used in pregnant women and children younger than 7 years (in whom tetracyclines can stain the permanent teeth).

Antibiotic therapy can result in accelerated phagocytosis of spirochetes by neutrophils and a transient elevation in tumor necrosis factor–α (TNF-α) and interleukin (IL)-6, IL-8, and IL-10. The clinical manifestation is a Jarisch-Herxheimer reaction,[12] which is typically characterized by a 1° C rise in body temperature, rigors, a rise in blood pressure followed by a fall, and transient leukopenia about 2 to 3 hours after treatment. This reaction is more common in louse-borne disease and less common in tick-borne disease. Death as a result of shock from the Jarisch-Herxheimer reaction occurs rarely. In small numbers of patients with louse-borne relapsing fever, anti–TNF-α antibodies have been effective in prevention.

PREVENTION

Prevention of louse-borne relapsing fever hinges on improving hygienic conditions, delousing affected areas, and antibiotic treatment of patients and close contacts. Tick-borne relapsing fever can be prevented by reducing the risk of contact with rodents and ticks, including repair of structural flaws in cabins and other residences so rodents cannot nest in or around them, as well as spraying infested indoor environments. Tick-bite screening and prophylactic treatment with doxycycline (a single 200-mg dose)[11] in highly endemic areas has been reported to be practical, safe, and about 75% effective for preventing tick-borne relapsing fever.

PROGNOSIS

Epidemics of louse-borne relapsing fever have been reported to have mortality rates approaching 40%, with as much as 5% of the mortality related to Jarisch-Herxheimer reactions with treatment. Mortality from tick-borne disease is less than 5%. Autopsies of patients with louse-borne disease have documented intracranial hemorrhage, brain edema, bronchopneumonia, hepatic necrosis, and splenic infarcts.

298 LEPTOSPIROSIS

DAVID A. HAAKE

DEFINITION

Leptospirosis is a zoonotic bacterial infection caused by pathogenic spirochetes belonging to the genus *Leptospira*. It has a global distribution and is most prevalent in tropical areas with poor urban infrastructure and heavy rainfall. Leptospirosis is transmitted to humans either by direct contact with infected animals or by contact with soil or water contaminated by rodent urine. The disease ranges in severity from a relatively mild, self-limited infection to a life-threatening, sepsis-like syndrome characterized by the triad of jaundice, acute renal insufficiency, and bleeding, sometimes complicated by severe pulmonary hemorrhage.

The Pathogen

The name *Leptospira* comes from the Greek words for thin (*leptos*) and coil (*speira*). These highly motile bacterial spirochetes measure 0.1 microns in diameter and 6 to 20 microns in length. The trailing end may be hooked when translocating through a liquid medium, thereby giving the organism the shape of a question mark and inspiring the naming of the species *Leptospira interrogans* (Fig. 298-1), which most commonly causes human infection. However, 64 different species have been described, including pathogens and commensals of host animals as well as free-living, saprophytic species.[1] Leptospiral pathogens include over 25 serogroups and 250 serovars that differ by geographic distribution and host specificity. Leptospiral genomes are characterized by extensive interspecies horizontal gene transfer, which may facilitate adaptation to a broad range of ecologic niches and reservoir host animals. Colonization of the renal tubules of infected animals leads to urinary shedding of the organism in soil and water.

EPIDEMIOLOGY

Leptospirosis, which is the most widespread zoonosis (Chapter 303) and a leading cause of morbidity and mortality worldwide, is estimated to cause about 1 million clinical infections and nearly 60,000 deaths each year. Even these numbers are likely to be underestimates, however, because leptospirosis predominantly affects medically underserved populations and is frequently misdiagnosed as dengue (Chapter 352), malaria (Chapter 316), or influenza (Chapter 332) when it presents as a nonspecific acute febrile illness.

Transmission to humans frequently involves rodent reservoir hosts, especially the urban brown rat, *Rattus norvegicus*, in which the organism is associated with high rates of renal colonization. *R. norvegicus* appears to become infected with *L. interrogans* serovar Icterohaemorrhagiae early in life and persistently sheds leptospires in its urine. Other sources include both domestic and wild animals.[2]

Leptospirosis is endemic in many developing countries with high temperatures and rainfall, such as India, Malaysia, and Brazil.[3] Leptospirosis is predominantly a disease of poverty, with high rates of exposure and infection in vulnerable populations living in settings where rodents are able to gain access to human living spaces and where urban flood control infrastructure is inadequate. In such settings, leptospirosis infections spike during heavy rainfalls when rodents are forced from their burrows and leptospires are washed into floodwaters.[4] The incidence of leptospirosis is likely to increase as extreme rainfall events become more common as a result of climate change.

Leptospirosis infections also occur among individuals taking part in adventure travel. For example, participants in the 2000 "Eco-Challenge" in Malaysian Borneo had a 42% infection rate of leptospirosis, presumably because participants floated down the Segama River, which had become swollen by heavy rainfall in the days leading up to the competition. Individuals with prolonged exposure to contaminated water are at higher risk of infection, particularly when cutaneous abrasions are present. The HLA-DQ6 haplotype is an independent risk factor for human infection.

PATHOBIOLOGY

Leptospiral morphology, motility, and invasiveness facilitate penetration of abraded skin and mucous membranes followed by dissemination via the blood stream. Leptospires have a surprisingly rich arsenal of mechanisms to evade detection and killing by the innate immune system.[5] Leptospiral proteins bind lipopolysaccharide and peptidoglycan, thereby shielding these target molecules from detection by the innate immune system.[6] Leptospiral surface proteins bind complement regulators, which renders them resistant to complement-mediated killing. Dissemination to multiple organs, including the kidney and brain, is facilitated by disruption of tissue barriers such as endothelial cell junctions. Leptospires are found in the hepatic sinusoids, and the resulting hepatocellular disruption leads to bile leakage and jaundice. Disruption of tissue barrier and impaired hemostasis mechanisms, including thrombocytopenia and coagulation disorders, leads to bleeding in various organs, most notably the lungs.

Leptospirosis is a biphasic illness consisting of an initial leptospiremic phase followed by an immune phase characterized by formation of agglutinating antibodies and clearance of organisms from the blood stream. During the leptospiremic phase, organisms disseminate to various organs and are found in the blood and urine. Shedding of organisms in the urine is the result of colonization of the renal tubules. Proximal renal tubular infection causes impaired sodium and water reabsorption due to decreased expression of transporter proteins, thereby leading to potassium wasting and fluid loss. Urinary shedding is transient in humans due to clearance by the inflammatory response, which is observed histopathologically as interstitial nephritis with cellular infiltration and edema of the renal interstitium (Fig. 298-2). During the subsequent immune phase, generalized activation of the immune system may occur, resulting in a sepsis-like syndrome and multiorgan system failure.

CLINICAL MANIFESTATIONS

The incubation period for leptospirosis is highly variable but appears to be about 6 to 29 (median 15) days. Most cases of leptospirosis are mild and self-limited and can even be asymptomatic. In symptomatic patients, initial manifestations (Fig. 298-3) typically include sudden onset of fever, chills, and headache.[7] The headache is often described as a severe, bitemporal, frontal throbbing headache accompanied by retro-orbital pain and photophobia. Muscle pain and tenderness is common and characteristically involves the

ABSTRACT

Leptospirosis is a zoonosis caused by spirochetal bacteria belonging to the genus *Leptospira*. It has a global distribution and is maintained in nature by chronic renal colonization of carrier animals, especially rodents. Infections typically occur after occupational or recreational exposure to water or soil that has been contaminated with rodent urine. In resource limited countries, outbreaks of leptospirosis occur regularly in urban settings after heavy rainfall and flooding. Early leptospirosis often presents with the abrupt onset of fever, headache, myalgias, and conjunctival suffusion, but it can be difficult to distinguish from other acute febrile illnesses. A high index of suspicion based on signs, symptoms, and epidemiologic exposure is required to identify patients who may benefit from early antimicrobial therapy. Severe leptospirosis is characterized by the triad of jaundice, acute renal insufficiency, and bleeding (Weil disease). Polymerase chain reaction assays of serum and urine have high sensitivity for detecting early infection. Serologic tests are helpful when positive but have lower sensitivity during the first week of illness. Blood cultures can helpful early in the course of the disease, and urine cultures can be helpful later in the course. For mild disease, doxycycline or azithromycin is recommended. For more severe disease, intravenous penicillin, ampicillin, or ceftriaxone is indicated. Patients who have early renal disease with high-output renal dysfunction and hypokalemia should receive aggressive volume repletion and potassium supplementation. Patients with oliguric renal failure should undergo rapid initiation of hemodialysis or peritoneal dialysis. Leptospirosis can be prevented by limiting direct contact with infected animals and indirect contact with urine-contaminated soil and water. Prophylactic antibiotics or immunization can be effective in situations in which high-risk exposure cannot be avoided.

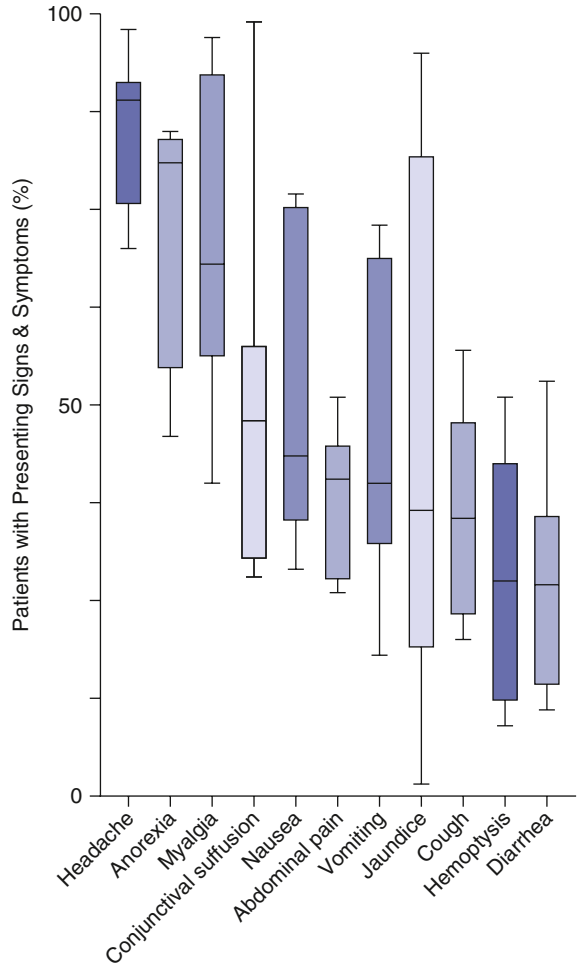

FIGURE 298-3. Signs and symptoms of leptospirosis. Box plots showing the percentage of presenting signs and symptoms of leptospirosis across nine large case series. (Data from Levett, P. N. and Haake, D. A., "Leptospira Species [Leptospirosis]," Table 239.2. In: Mandell, G. L., Bennett, J. E., and Dolin, R., eds. Principles and Practices of Infectious Diseases, Ninth Edition, Elsevier, Amsterdam, Chapter 240 [2020].)

FIGURE 298-4. Conjunctival suffusion and scleral icterus in a 37-year-old man with Weil disease. Conjunctival suffusion is a characteristic sign of leptospirosis. (Reproduced from Jansen A, Schneider T. Weil's disease in a rat owner. *Lancet Infect Dis*. 2011;11:152.)

calves and lower back. Ocular findings (Fig. 298-4) include conjunctival suffusion (a pathognomonic injection without exudate), subconjunctival hemorrhages, and icterus.[8] Nonproductive cough can occur in up to about 50% of cases. Gastrointestinal symptoms including nausea, vomiting, diarrhea, and abdominal pain are common and, together with a nonoliguric renal insufficiency, may lead to poor fluid intake and exacerbation of dehydration and precipitation of oliguric renal failure. Abdominal pain may indicate pancreatitis, although elevations of serum amylase levels may occur without pancreatitis in the setting of reduced creatinine clearance.

TABLE 298-1 LEPTOSPIROSIS CASE DEFINITIONS

Suspect Case: Acute febrile illness (≥38.5° C) and/or severe headache with:
- Myalgia
- Prostration and/or conjunctive suffusion, and
- History of exposure

Probable Case (clinical definition): Suspect case with any **two** of the following:
- Calf tenderness
- Cough with or without hemoptysis
- Shortness of breath
- Skin rash
- Jaundice
- Hemorrhagic manifestations
- Meningeal irritation
- Anuria/oliguria and/or proteinuria
- Cardiac arrhythmias

Probable Case (laboratory definition)**:** Suspect case with a positive rapid IgM test and/or any three of the following:
- Urinary findings: proteinuria, white blood cells, blood
- Relative neutrophilia (>80%) with lymphopenia
- Platelets <100,000/μL
- Elevated serum bilirubin (>2 mg); liver enzymes moderately raised

Confirmed Case: Suspect or probable case with any one of the following:
- Isolation of leptospires from clinical specimens
- Positive PCR result
- Seroconversion from negative to positive or four-fold rise in MAT titer
- MAT titer ≥400 in a single sample

Ig = immunoglobulin; MAT = microscopic agglutination test; PCR = polymerase chain reaction.

A maculopapular erythematous rash may occur after the onset of symptoms, particularly in the pretibial area of the legs. However, cutaneous manifestations occurring early in the course of an acute febrile illness are more common in dengue (Chapter 352) and chikungunya fever (Chapter 352).

Infection by pathogenic species and serovars, such as *Leptospira interrogans*, serovar Icterohaemorrhagiae, may result in more serious illness in about 10% of patients. The combination of jaundice, renal failure, and hemorrhage corresponds to the original description of leptospirosis as Weil disease. Bleeding manifestations are usually mild and limited to findings such as petechiae and ecchymoses, but some patients have severe gastrointestinal or pulmonary hemorrhage.

Multiorgan involvement of the liver, kidney, lungs,[9] and brain represents the disseminated infection. Acute hemolytic anemia, which can contribute to jaundice, is more common in patients who have glucose 6 phosphate dehydrogenase deficiency. Early infection may be associated with non-oliguric renal insufficiency, potassium wasting, and hypokalemia.

DIAGNOSIS

A high index of suspicion is needed to identify patients who may benefit from early antimicrobial therapy. A provisional diagnosis of acute leptospirosis should be based primarily on clinical and epidemiologic grounds so as to enable early treatment. Leptospirosis should be suspected in patients who have an acute febrile illness (≥38.5° C) and/or severe headache and who have relevant risk factors and/or a history of exposure, particularly if myalgia, prostration, and/or conjunctival suffusion are present (see Table 298-1). Additional clinical manifestations that support the diagnosis include calf tenderness, cough with or without hemoptysis, shortness of breath, jaundice, hemorrhage, meningeal irritation, oliguria and/or proteinuria, and cardiac arrhythmias.

The most sensitive approach to the laboratory diagnosis of acute leptospirosis, which is DNA amplification methods on blood, urine, or cerebrospinal fluid,[10] is now often feasible even in resource-poor settings.[11] Leptospires may be cultured directly from clinical specimens, especially blood or urine, using specialized media if specimens are obtained early in the course of disease and prior to administration of antibiotics. Serologic tests may initially be negative and should not be relied on to diagnose acute infection. IgM antibodies usually become detectable during the first week of illness; seroconversion from a negative to a positive serology, a four-fold rise in titer, or a single titer of 1 : 400 or more is diagnostic. Procalcitonin and C-reactive protein levels are elevated in leptospirosis and are valuable to differentiate leptospirosis from viral infections such as dengue fever (Chapter 352).[12,13]

Many patients have leukocytosis (greater than 80% neutrophilic), thrombocytopenia, and coagulopathies, including an elevated international normalized ratio, active partial thromboplastin time, and D-dimer levels. Lumbar puncture in patients with headache often shows an aseptic meningitis, with

increased cells (predominantly lymphocytes) and an elevated protein level but a normal glucose level. Patients typically have mild to moderate elevations in liver aminotransferase level elevation of direct (conjugated) bilirubin in more severe disease. Renal findings can include pyuria, hematuria, and elevated urine protein levels as well as elevations in serum blood urea nitrogen and creatinine levels. Bilirubin and liver enzymes are typically moderately elevated. Diffuse pulmonary ground-glass opacities and airspace nodules on chest computed tomography reflect diffuse alveolar hemorrhage.

Differential Diagnosis

Early leptospirosis can initially be difficult to distinguish from a variety of acute febrile illnesses. The differential diagnosis depends on other concurrent diseases in the geographic area, most frequently malaria (Chapter 316), dengue (Chapter 352),[14] typhoid fever (Chapter 284), melioidosis (Chapter 282), scrub typhus (Chapter 302), and rickettsial diseases (Chapter 302). Other diseases to consider include influenza (Chapter 332), acute viral hepatitis (Chapter 134), yellow fever (Chapter 351), bacterial and viral meningitis (Chapter 381), bacterial sepsis (Chapter 94), Zika virus (Chapter 352), Chikungunya virus (Chapter 352), and Hantavirus infection (Chapter 303). Useful diagnostic clues are conjunctival suffusion, muscle tenderness, and pulmonary hemorrhage.

TREATMENT

Many cases of leptospirosis are relatively mild and self-limited. However, if patients are sick enough to come to medical attention, early empiric antimicrobial therapy should be initiated to minimize symptoms and reduce urinary shedding. Leptospires are susceptible to a wide variety of antimicrobials.[15] Adult outpatients should be treated with doxycycline (100 mg orally twice daily for 7 days) or azithromycin (500 mg orally once daily for 3 days). Pregnant women should be treated with azithromycin (500 mg orally once daily for 3 days) or amoxicillin (500 mg orally three times daily for 7 days). Inpatients should be treated with penicillin (1.5 mU IV every 6 hours), ampicillin (0.5 to 1 g IV every 6 hours), or ceftriaxone (1 g IV every 24 hours) for 7 days.[A1] A Jarisch-Herxheimer reaction (e.g., fever, headache, chills or rigors, vomiting, tachycardia, and even hypotension; see Chapter 295) may occur, depending on the serovar that is causing infection and the time from onset of symptoms to the initiation of antimicrobial therapy.

Patients should be assessed for fluid balance and ability to hydrate orally. Supportive care with intravenous hydration may be indicated to correct dehydration and prevent acute tubular necrosis and renal failure. Potassium supplementation should be included for patients with hypokalemia. When oliguric renal failure occurs, prompt initiation of peritoneal dialysis, which is usually needed only on a short-term basis, or hemodialysis can be lifesaving.

Patients with severe pulmonary hemorrhage syndrome (Chapter 79) who have poor pulmonary compliance benefit from protective ventilation strategies based on low tidal volumes (<6 mL/kg) and high postexpiratory end pressures (Chapter 90). Extracorporeal membrane oxygenation has been used successfully to manage respiratory failure caused by leptospirosis.

PREVENTION

The most important prevention measures involve avoidance or reduction of high-risk exposures. Contact with potentially infected animals or with potentially contaminated soil and water should be reduced. Personal protective equipment should include boots, goggles, overalls, and gloves that are impermeable to liquids. Rodent control measures and immunization of domestic animals can be effective in endemic settings. Individuals who participate in adventure races or recreational water sports or who swim in natural bodies of water such as lakes and streams may be candidates for prophylaxis with doxycyline 200 mg or azithromycin 500 mg orally weekly beginning 1 to 2 days before exposure. Such antimicrobial prophylaxis and immunization have also been used in highly exposed workers in endemic settings[A2] and in the setting of flooding[A3] and large-scale epidemics.

PROGNOSIS

Many cases of leptospirosis are relatively mild and self-limited, but it can be difficult to predict which patients will benefit from more aggressive interventions. The risk of mortality for infection complicated by hepatorenal failure is 10%. In one study of 370 hospitalized patients, the overall case fatality rate was 24%; independent odds ratios were 6.0 for pulmonary involvement, 3.0 for oliguria, 2.3 for a creatinine level greater than 3.0 mg/dL, 2.2 for age older than 40 years, and 2.2 for a platelet count less than 70,000/μL. The odds ratio of death is also about 11-fold higher in patients over age 60 years compared with patients ages 19 years or less. Severe pulmonary hemorrhage syndrome is an ominous development and is associated with an increased mortality rate of up to 50%, and altered mental status is the strongest predictor of death.

299 TUBERCULOSIS

THOMAS C. BAILEY AND JENNIFER A. PHILIPS

DEFINITION

Tuberculosis (TB) is a granulomatous disease caused by the slow-growing, acid-fast bacillus *Mycobacterium tuberculosis*. Prior to the emergence of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2; Chapter 337), TB was the leading infectious disease cause of death worldwide. People become infected with *M. tuberculosis* by inhaling infectious organisms through aerosol transmission from a person who has active TB.

The Pathogen

The *M. tuberculosis* complex is a group of highly genetically related species that cause tuberculosis in humans, livestock, and wildlife. *M. tuberculosis* and *Mycobacterium africanum*, which cause TB in humans, are obligate human pathogens with no known environmental reservoir. Other members of the *M. tuberculosis* complex cause infection in distinct mammalian hosts, including *Mycobacterium bovis* in cattle, *Mycobacterium caprae* in goats and sheep, *Mycobacterium pinnipedii* in sea lions, and *Mycobacterium microti* in voles.[1] Although humans with active TB can infect animals, subsequent transmission of *M. tuberculosis* from animal to animal or back to humans is extremely rare. Animal-adapted members of the *M. tuberculosis* complex can also infect humans, most often when *M. bovis* (or *Mycobacterium orygis* in Africa and Southeast Asia) is retransmitted from infected cattle or unpasteurized dairy products, but subsequent human-to-human transmission is rare. Members of the *M. tuberculosis* complex likely arose from a common ancestor that resembles *Mycobacterium canettii*, which is a species that is phylogenetically positioned between mammalian pathogens and environmental mycobacteria and that has been isolated in rare cases of human tuberculosis from the Horn of Africa.

M. tuberculosis is a nonmotile, non-spore-forming, facultative anaerobe that is rod-shaped and approximately 2 to 4 μm in length. Unique features of *M. tuberculosis* include its "waxy" cell envelope, extremely slow growth, and ability to replicate intracellularly. *M. tuberculosis* doubles every 18 to 24 hours, so culturing the bacilli from clinical specimens may take weeks. The waxy coat prevents decolorization of carbol fuchsin stain after washing with strong acids, thereby leading to the characteristic "acid-fast" staining. A plasma membrane, peptidoglycan layer, arabinogalactan layer, outer membrane, and capsule comprise the cell envelope. The outer membrane contains mycolic acids and a complex array of unique lipids, such as phthiocerol dimycocerosate, phenolic glycolipids, trehalose dimycolates, and sulfolipids. This complex cell envelope, which is important for pathogenesis and transmission, also creates a formidable barrier to the entry of antibiotics.[2] The ability of *M. tuberculosis*

299 TUBERCULOSIS

THOMAS C. BAILEY AND JENNIFER A. PHILIPS

DEFINITION

Tuberculosis (TB) is a granulomatous disease caused by the slow-growing, acid-fast bacillus *Mycobacterium tuberculosis*. Prior to the emergence of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2; Chapter 337), TB was the leading infectious disease cause of death worldwide. People become infected with *M. tuberculosis* by inhaling infectious organisms through aerosol transmission from a person who has active TB.

The Pathogen

The *M. tuberculosis* complex is a group of highly genetically related species that cause tuberculosis in humans, livestock, and wildlife. *M. tuberculosis* and *Mycobacterium africanum*, which cause TB in humans, are obligate human pathogens with no known environmental reservoir. Other members of the *M. tuberculosis* complex cause infection in distinct mammalian hosts, including *Mycobacterium bovis* in cattle, *Mycobacterium caprae* in goats and sheep, *Mycobacterium pinnipedii* in sea lions, and *Mycobacterium microti* in voles.[1] Although humans with active TB can infect animals, subsequent transmission of *M. tuberculosis* from animal to animal or back to humans is extremely rare. Animal-adapted members of the *M. tuberculosis* complex can also infect humans, most often when *M. bovis* (or *Mycobacterium orygis* in Africa and Southeast Asia) is retransmitted from infected cattle or unpasteurized dairy products, but subsequent human-to-human transmission is rare. Members of the *M. tuberculosis* complex likely arose from a common ancestor that resembles *Mycobacterium canettii*, which is a species that is phylogenetically positioned between mammalian pathogens and environmental mycobacteria and that has been isolated in rare cases of human tuberculosis from the Horn of Africa.

M. tuberculosis is a nonmotile, non-spore-forming, facultative anaerobe that is rod-shaped and approximately 2 to 4 μm in length. Unique features of *M. tuberculosis* include its "waxy" cell envelope, extremely slow growth, and ability to replicate intracellularly. *M. tuberculosis* doubles every 18 to 24 hours, so culturing the bacilli from clinical specimens may take weeks. The waxy coat prevents decolorization of carbol fuchsin stain after washing with strong acids, thereby leading to the characteristic "acid-fast" staining. A plasma membrane, peptidoglycan layer, arabinogalactan layer, outer membrane, and capsule comprise the cell envelope. The outer membrane contains mycolic acids and a complex array of unique lipids, such as phthiocerol dimycocerosate, phenolic glycolipids, trehalose dimycolates, and sulfolipids. This complex cell envelope, which is important for pathogenesis and transmission, also creates a formidable barrier to the entry of antibiotics.[2] The ability of *M. tuberculosis*

ABSTRACT

Mycobacterium tuberculosis, the causative agent of tuberculosis (TB), is estimated to have infected one quarter of the world's population and is a leading cause of infectious disease death worldwide. *M. tuberculosis* is spread by aerosol transmission. Most often, infected individuals develop latent TB infection, but approximately 10% of individuals will develop active disease, either due to progressive primary infection or reactivation of latent infection. Interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α), and CD4 T cells are critical in host immune control of infection. In individuals in whom these responses are impaired, such as inborn errors in the IL-12-IFN-γ signaling axis, treatment with anti–TNF-α agents, and HIV coinfection, the risk of developing active infection and disseminated disease is markedly increased. Active TB is most often pulmonary, but a wide variety of extrapulmonary disease manifestations also occur. The challenges associated with diagnosing and treating TB are compounded by HIV coinfection and drug resistance. As a result, TB remains an enormous global health threat.

KEYWORDS

Mycobacterium tuberculosis
latent tuberculosis infection

tuberculosis-associated immune reconstitution inflammatory syndrome
multidrug-resistant TB
extensively drug-resistant TB

to withstand adverse conditions and disrupt host immunity depends upon this unique cell envelope.

M. tuberculosis is classified into distinct phylogenetic lineages that are thought to have originated in the Horn of Africa and spread to other parts of the world in association with human migration. The more ancestral strains (lineages 1 and 5 to 7) are geographically restricted. Lineages 5 and 6 are *M. africanum* lineages found almost exclusively in West Africa. The "modern" *M. tuberculosis* lineages (lineages 2 to 4) are responsible for the global epidemic of TB. Although all lineages cause the same spectrum of disease, lineage appears to impact pathogenesis and epidemiologic spread.[3] For example, certain lineage 2 strains are more likely to cause severe pulmonary infection, to develop drug resistance more rapidly, and to be more transmissible. Lineage identification is not part of routine clinical care, but more detailed strain typing is useful in investigations of outbreaks to establish whether cases are epidemiologically linked. Strain typing can be performed by restriction fragment length polymorphism of the insertional element IS6110, spoligotyping, mycobacterial interspersed repetitive unit analysis, and whole-genome sequencing. In addition, genotyping can be used to distinguish relapse from reinfection in high burden settings and in relatively rare instances of laboratory cross-contamination of diagnostic specimens.

EPIDEMIOLOGY

The World Health Organization (WHO) estimates that 1.7 billion people, a quarter of the world's population, are latently infected with *M. tuberculosis*. In 2018, an estimated 10 million new active cases of TB and 1.2 million deaths occurred worldwide, with the majority occurring in low- and middle-income countries.[4] As a result, TB was the leading infectious disease killer prior to being overtaken by SARS-CoV-2 during the coronavirus disease 2019 (COVID-19) pandemic. Worldwide, 35% of cases occur in women, and the prevalence of disease peaks in young adults. HIV has a profound impact on the epidemiology of TB: 10% of TB cases worldwide occur in people with HIV infection, and TB is the leading cause of death among persons living with HIV (Chapter 358).

The risk of TB depends upon the country of origin. The prevalence of latent TB infection is estimated to be 4% in the United States but exceeds 20% in Southeast Asia, the Western Pacific, and Africa.[5] The same geographic disparity is seen for active disease. In Southeast Asia, the incidence of TB is 220 per 100,000 persons per year, whereas most high-income countries have an incidence of less than 10 per 100,000 persons per year (Fig. 299-1). In high-burden settings with substantial ongoing transmission, active TB most often occurs because of progression during the first 2 years after initial infection. In low burden settings, however, active TB is more likely to result from reactivation of more long-standing latent infection. Although most people develop an adaptive immune response that controls infection, this response does not prevent reinfection. In high-burden settings, individuals previously treated for TB are at increased risk of being infected with a new strain of *M. tuberculosis* compared with individuals without a TB history.

For over 100 years, the incidence of TB has declined in the United States, with the notable exception of 1984 to 1992, when the rise of the HIV epidemic led to an increasing incidence. In 2019, the 8920 reported active cases (2.7 per 100,000 persons) were the lowest since reporting began in the early 1950s but still far from the goal of eliminating TB, which is generally defined as an incidence below one case per million people per year. In the United States, the majority (about 70%) of TB cases occur in immigrants from high-incidence countries. This elevated risk of TB disease persists in immigrants from high-prevalence countries long after their arrival in the United States; for example, approximately 45% of new TB cases among foreign-born residents were diagnosed 10 or more years after they first arrived in the United States. Other risk factors for TB infection and progression to active disease include having household contact with active pulmonary TB, HIV disease or other causes of immunosuppression, residence in a homeless shelter or correctional faculty, diabetes mellitus, and underlying lung disease (Table 299-1). In general, people who are at highest risk for active TB disease are individuals who were recently infected and who are immunosuppressed. These risk factors also inform the interpretation of tuberculin skin testing and treatment strategies for latent TB (see later).

The worldwide problem of TB is compounded by drug resistance. In 2019, about 3% of new TB cases and 18% of previously treated cases had drug-resistant TB. Multidrug-resistant TB (resistant to both isoniazid and rifampin) exists worldwide, with the majority of cases occurring in India (27%), China (14%), and Russia (8%). Extensively drug-resistant (XDR) TB, which is resistant to isoniazid, rifampin, fluoroquinolones, and at least one of the three second-line injectable agents, is estimated to occur in about 10% of patients with multidrug-resistant TB. The epidemic of drug resistance is driven both by transmission of drug-resistant isolates and the acquisition of drug resistance due to inappropriate treatment.[6]

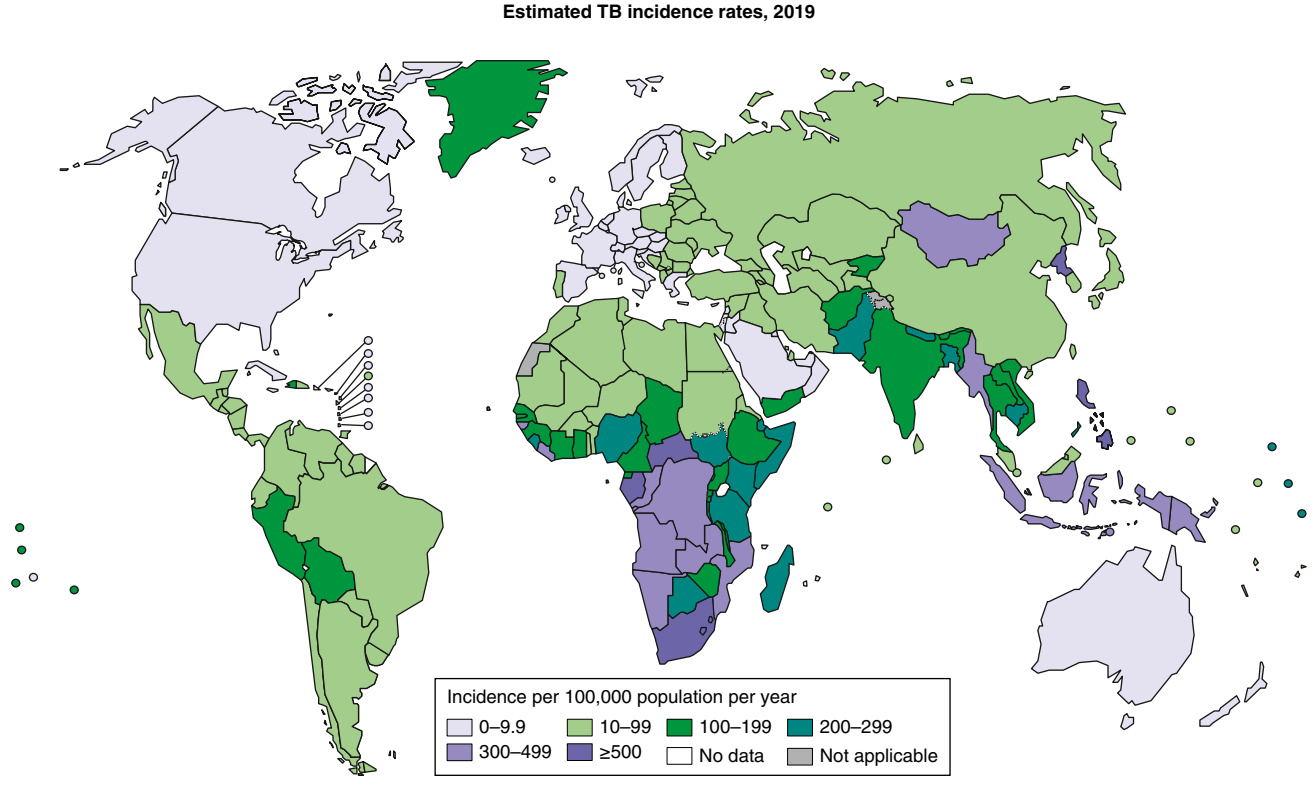

FIGURE 299-1. Estimated TB incidence rates, 2019 (from Global Report, 2020). The severity of national TB epidemics in terms of the annual number of incident TB cases relative to population size (the incidence rate) in 2019. High-income countries and low-income countries had widely divergent TB incidence rates. (Reprinted from the Global tuberculosis report 2020. Geneva: World Health Organization; 2020. TABLE 299-1 RISK FACTORS FOR TUBERCULOSIS

RISK FACTOR	INCREASED RISK OF RECENT INFECTION*	INCREASED RISK OF PROGRESSION TO ACTIVE DISEASE	DEFINITION OF A POSITIVE TB SKIN TEST
Household contact of active pulmonary TB	X		≥5 mm
Solid organ transplant recipient, immunosuppressive treatment (TNF-α inhibitors, prednisone >15 mg/day for >1 month), fibrotic lesion on chest radiograph consistent with prior TB		X	≥5 mm
HIV infection		X	≥5 mm
Birth or extended residence in higher-prevalence countries; persons using nonprescription injectable drugs who are known to be HIV-negative; children under 5 years old; children and adolescents exposed to adults in high-risk categories	X		≥10 mm
Residents or employees in hospitals, homeless shelters, correctional facilities, nursing homes, residences for HIV-infected	X		≥10 mm
<90% IBW or BMI ≤20; cigarette smoking; silicosis; diabetes mellitus (particularly insulin-dependent or poorly controlled); end-stage renal disease; post-gastrectomy or jejuno-ileal bypass; carcinoma of the head and neck; lung cancer; lymphoma; leukemia		X	≥10 mm
None			≥15 mm

*Recent infection itself also increases the risk of progressing to active disease.
BMI = body mass index; HIV = human immunodeficiency virus; IBW = ideal body weight; TNF = tumor necrosis factor.

In response to the rise in HIV/TB coinfections and multidrug-resistant *M. tuberculosis* in 2013, the WHO declared TB a global public health emergency and developed the End TB Strategy. Unfortunately, the COVID-19 pandemic has interfered with these efforts. TB services have been disrupted by worldwide lockdowns, overwhelmed health care systems, and the reallocation of health care workers and resources to care for COVID-19 patients. In 2020, 1.4 million fewer TB cases were reported worldwide than in 2019, almost certainly owing to underreporting rather than a true reduction in incidence. The reduction in detection and, hence, in prompt treatment in 2020 is projected to result in 0.5 million excess TB deaths, with worldwide TB mortality climbing back to levels last seen in 2010.[7]

PATHOBIOLOGY

M. tuberculosis effectively disarms the innate immune response, persists in the face of adaptive immunity, and disseminates, thereby leading to a wide spectrum of infectious manifestations. The infection cycle begins when *M. tuberculosis* is transmitted from a person with active pulmonary TB through aerosolized particles that are small enough to reach the alveoli (1 to 5 μM; Fig. 299-2). The degree of infectiousness depends upon the severity of cough, which is promoted by sulfolipid in the mycobacterial cell envelope, and the extent of bacterial burden.[8] Patients with cavitary lesions, which can have 10^7 to 10^9 bacilli, are the most infectious. Patients who do not have visible acid-fast bacilli on sputum smears are much less likely to transmit, but they still can infect others. Patients with HIV are less likely to develop cavitary disease, to be smear positive, or to transmit infection. On average, infectious individuals will infect 3 to 10 people per year. In household settings, where exposure may be intense and prolonged, 25 to 50% of contacts become infected.

A central feature of the pathogenesis of *M. tuberculosis* is its ability to survive and grow in host phagocytic cells that normally clear infection.[9] When *M. tuberculosis* bacilli reach the distal alveoli, they are first taken up by alveolar macrophages, which normally kill microbes and clear debris, but they are poorly equipped to handle *M. tuberculosis* (Fig. 299-2). Over time, monocyte-derived macrophages, interstitial macrophages, and neutrophils are recruited to the site of infection, but they also fail to control *M. tuberculosis* replication. Infected dendritic cells travel to the draining lymph node, where presentation of *M. tuberculosis* antigens leads to priming and expansion of antigen-specific T cells, which return to the infected lung. Once an adaptive immune response develops, T cells, B cells, and activated macrophages form the characteristic granuloma, and bacterial control is established. The interval from the initial infection to the development of a positive tuberculin skin test and/or IFN-γ release assay (IGRA) is usually between 2 and 8 weeks. This delay in the adaptive immune response allows *M. tuberculosis* to establish infection, which is often asymptomatic, and grow relatively unhindered for weeks.

Some individuals may sterilize the initial infection by virtue of their innate immune response by clearing bacilli before an adaptive immune response has time to develop. Individuals who are highly exposed to *M. tuberculosis* and appear to resist infection, as evidenced by persistently negative tuberculin skin test and/or IGRA, appear to have increased expression of metabolic pathways that respond to free fatty acids as well as increased *M. tuberculosis*–specific antibody responses.[10]

Granulomas, which are the histopathologic hallmark of *M. tuberculosis* infection, are thought to be important in preventing progressive disease after infection is established. Granulomas are an organized collection of macrophages, neutrophils, and lymphocytes. Macrophages within the granuloma can undergo an epithelioid transformation, form multinucleated giant cells, or become lipid-laden and "foamy" in appearance. Characteristically, the granulomas become necrotic and have a caseating appearance (like cheese). Over time, these granulomas calcify. CD4 T cells and TNF-α are critical in the formation of granulomas and to host protection. CD4 T cells secrete cytokines, such as IFN-γ, which promote the microbicidal activities of macrophages. Patients with CD4 T-cell dysfunction from HIV infection or patients treated with TNF-α inhibitors fail to form well-organized granulomas, and they are at high risk for developing active TB and disseminated infection. Similarly, patients who have inborn errors of IFN-γ signaling or who acquire IFN-γ neutralizing antibodies are highly susceptible to active disease and have a greater likelihood of developing disseminated and recurrent disease. Although granulomas prevent progressive infection, they may also facilitate bacterial persistence. Granulomas may enhance bacterial spread between aggregated macrophages, create an immunosuppressive environment, and keep CD4 T cells peripherally located, away from the more central, infected macrophages, thereby obstructing key immune cell interactions.[11] Even within an infected individual, different granulomas establish different degrees of immune control.[12]

Once infected, some patients will develop active disease over the first year of infection (termed progressive primary infection). However, most often, the initial infection, while disseminated, is controlled, thereby resulting in latent tuberculosis infection. Although the distinction between latent tuberculosis infection and active disease is extremely important clinically, the classification oversimplifies what is a more complex spectrum of infectious stages that include bacterial elimination and subclinical disease (Fig. 299-3). Some patients diagnosed with latent tuberculosis infection may sterilize the infection, but it is impossible, with current diagnostics, to tell whether the tubercle bacilli have been cleared by the adaptive immune response or are still viable but controlled.

Recent infection and a variety of conditions (see Table 299-1) increase the risk of active disease. HIV infection (Chapter 358) is the strongest known risk factor, even among individuals with relatively preserved CD4 T-cell counts. The majority of patients with active TB have no identified immunologic risk factor, but neutrophil-driven inflammation and a type I IFN response seem to promote progressive disease.

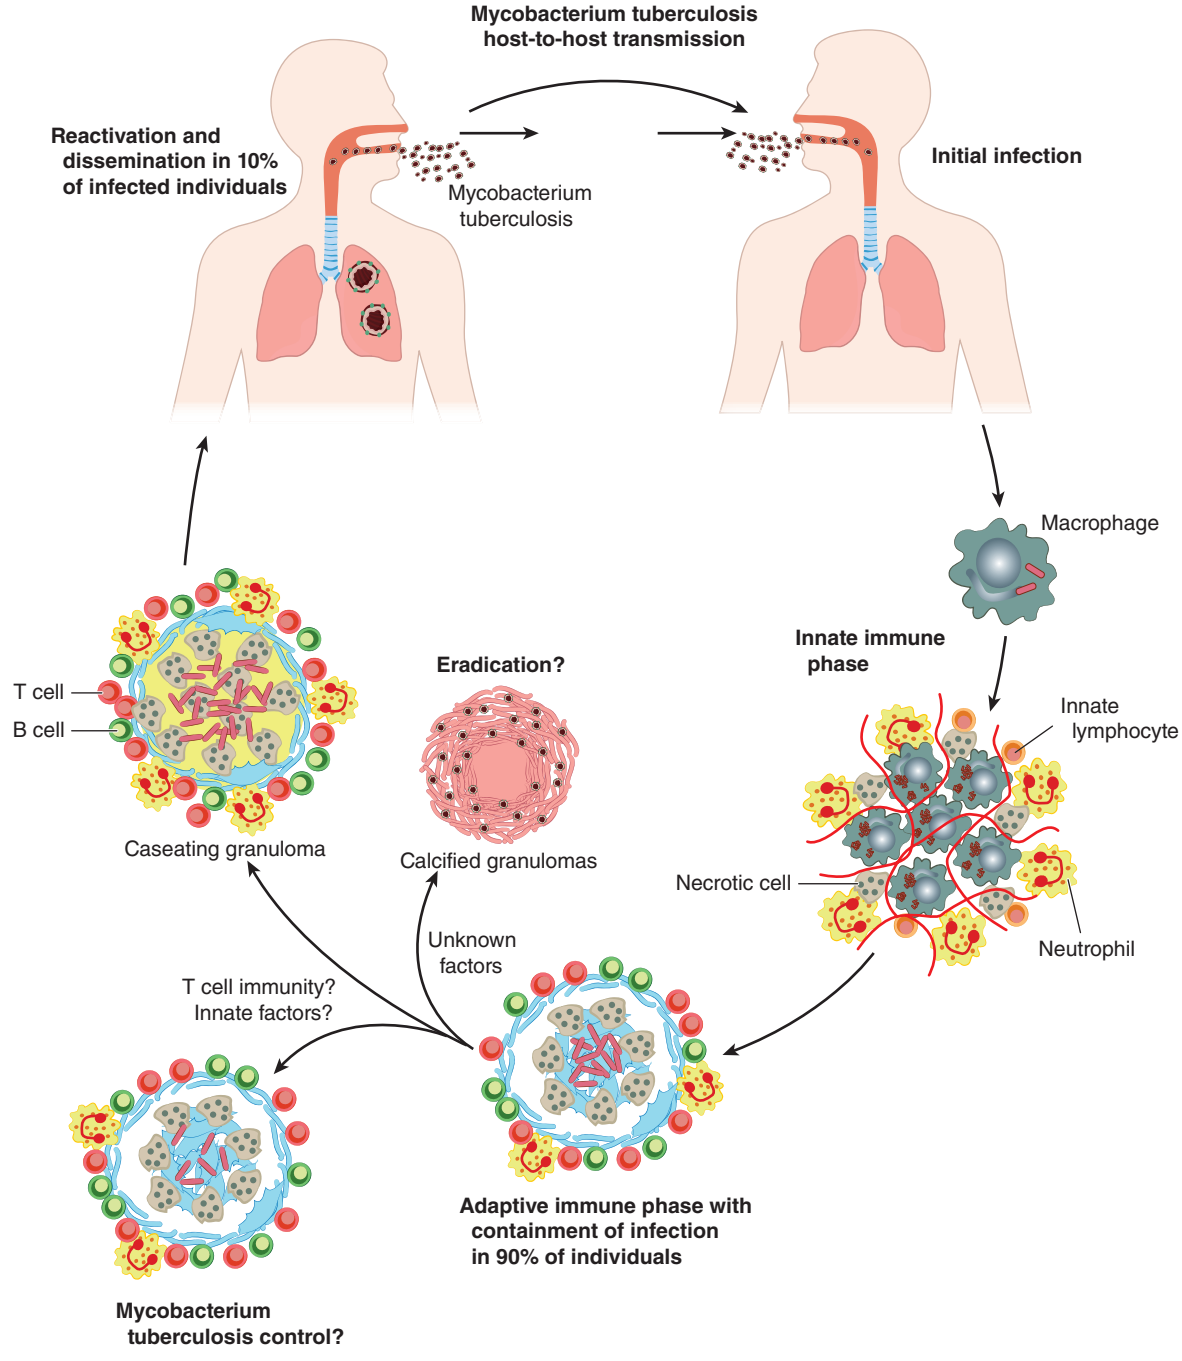

FIGURE 299-2. Pathogenesis of tuberculosis. *M. tuberculosis* is transmitted by aerosol and first infects alveolar macrophages in the distal alveoli. During the innate immune phase of the infection, inflammatory cells are recruited to the site of infection, but they fail to control bacterial replication. The adaptive immune response leads to control of infection, and well-organized granulomas are important in preventing dissemination. Approximately 10% of infected individuals will go on to develop active disease, which most often results in cavitary lung disease but can disseminate and involve any organ system. (From Claudio Nunes-Alves et al, *Nat Rev Micro*, 2014.)

CLINICAL MANIFESTATIONS

Primary Tuberculosis

Most cases of primary TB go clinically unrecognized and resolve without treatment. Individuals may develop fever, shortness of breath, nonproductive cough, and, rarely, erythema nodosum. Chest radiographs may show a small area of patchy opacity in the mid-lung fields (called a Ghon focus) with associated hilar lymphadenopathy (together called a Ghon complex) (Fig. 299-4A). Patchy, linear, or nodular parenchymal opacities may be seen. Lymphadenopathy, which is often unilateral, involves the hilum and right paratracheal nodes. Enlarged lymph nodes can cause bronchial compression, thereby leading to upper or middle lobe collapse. A transient pleural effusion may develop (Fig. 299-4B).

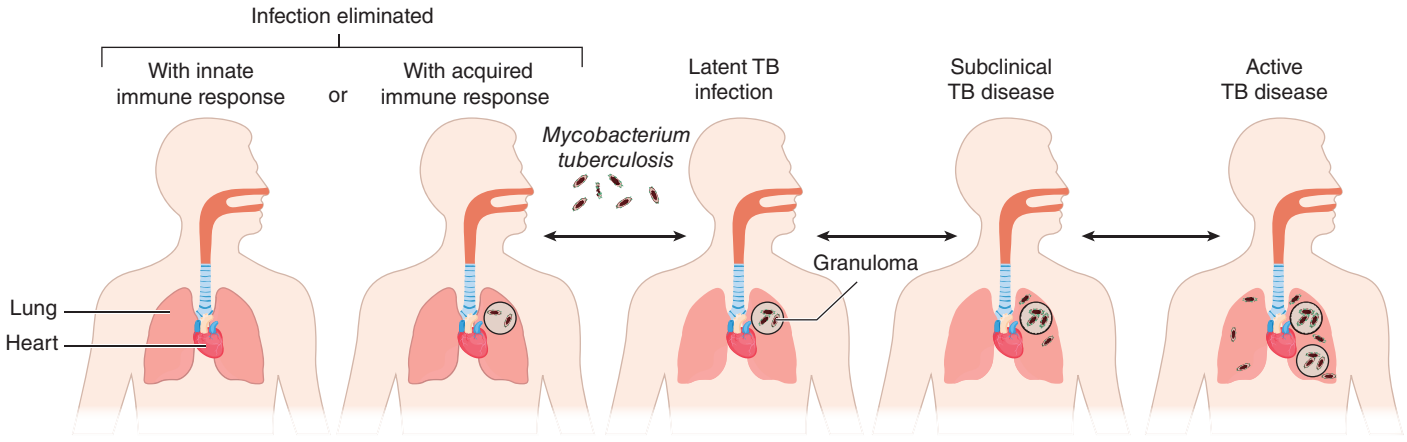
In most cases, the outcome of primary TB is latent tuberculosis infection. However, particularly in the absence of an effective adaptive immune response, primary infection can progress to pulmonary and extrapulmonary disease, including TB meningitis and miliary TB. Progressive primary infection is more likely to occur in children, the elderly, and the immunocompromised.

Latent Tuberculosis Infection

Most often, the immune response controls primary TB, thereby leading to clinically silent infection. Diagnosis of latent tuberculosis infection is made by demonstrating an immunologic response to *M. tuberculosis* antigens. Chest radiography may show evidence of prior infection; the Ghon complex may leave a calcified Ghon lesion in the mid-lung fields or calcified hilar nodes (when found together this is referred to as a Ranke complex). However, these radiographic findings are nonspecific and can also occur in other granulomatous infections, such as healed histoplasmosis (Chapter 308).

Pulmonary Tuberculosis

Active TB disease most often involves the lungs. When pulmonary TB occurs within the first year of infection, it is called progressive primary infection.



TST	Negative	Positive	Positive	Positive	Usually Positive
IGRA	Negative	Positive	Positive	Positive	Usually Positive
Culture	Negative	Negative	Negative	Intermittently positive	Positive
Sputum smear	Negative	Negative	Negative	Usually negative	Positive or negative
Infectious	No	No	No	Sporadically	Yes
Symptoms	None	None	None	Mild or none	Mild to severe
Preferred treatment	None	None	Preventive therapy	Multidrug therapy	Multidrug therapy

FIGURE 299-3. Spectrum of outcomes after TB infection. Clinically it is critical to distinguish latent TB infection from active disease in order to initiate the appropriate therapy. It is likely that other infection outcomes, including bacterial elimination and subclinical disease, also occur but are not possible to distinguish from latent TB infection with current diagnostic tools. IGRA = interferon gamma-release assay; TST = Mantoux tuberculin skin test. (From Pai, M. et al. and Raviglione M, Tuberculosis, *Nature Reviews Disease Primers*, Vol 2, 2016. This figure was also reproduced in Furin, Cox and Madhukar, *The Lancet*, DOI: https://doi.org/10.1016/S0140-6736(19)30308-3, an Elsevier journal.)

Pulmonary TB that occurs more distant to the initial infection is considered reactivation of latent tuberculosis infection (also termed "post-primary disease"). The most common symptom of pulmonary TB is a persistent cough, which can be productive or nonproductive and accompanied by fever, chills, night sweats, and weight loss; hemoptysis may occur in advanced disease. However, up to 25% of persons with culture-confirmed pulmonary TB do not report cough.

Physical examination findings are not specific. There may be abnormal breath sounds, such as post-tussive rales in the upper lung zones. Amphoric breath sounds can indicate a cavity. Lymphadenopathy is not common in immunocompetent adults with pulmonary TB.

Leukocytosis and anemia may be present. Progressive primary disease typically results in dense consolidation on chest radiography, with a predominant involvement of the middle and lower lobes (Fig. 299-4C,D), but the clinical and radiographic features of progressive primary and reactivation disease overlap. Reactivation pulmonary TB usually manifests as cavitary disease involving the apical and posterior segments of the right upper lobe and the apical-posterior segment of the left upper lobe, distant from the site of the primary infection (Fig. 299-5). Other radiographic findings can include fibrotic scars, loss of lung volume, and calcification. Endobronchial spread to lower portions of the lungs can lead to radiographic tree-in-bud opacities. Erosion into blood vessels or lymphatics can lead to dissemination and a miliary pattern.

In patients coinfected with HIV (Chapter 358), the clinical manifestations depend upon the degree of immune dysfunction. Disease in HIV-infected patients with relatively preserved immune function may be indistinguishable from disease in immunocompetent hosts, but as the degree of immunosuppression increases, the disease manifestations become more atypical. Persons living with HIV are less likely than immunocompetent individuals to be sputum-smear positive, less likely to have cavitary disease, and more likely to develop disseminated infection. Although most patients with pulmonary TB have abnormal chest radiographs, persons with HIV may have a normal chest radiograph despite smear-positive disease; a computed tomographic (CT) scan is more sensitive in these cases.

Extrapulmonary TB

Because primary infection is a disseminated process prior to immunologic control, extrapulmonary disease can affect nearly any organ system. Extrapulmonary disease can also mimic a wide array of other disorders, and it can be difficult to make a microbiologic diagnosis, since the bacterial burden may be relatively low and the site of infection may be difficult to access.

Pleural TB

Involvement of the pleural space can occur during primary infection or reactivation.[13] Most often TB pleuritis occurs when a small number of organisms gain access to the pleural space and elicit an inflammatory response. During primary infection, TB pleuritis may be clinically silent and resolve spontaneously, or it can result in cough, pleuritic chest pain, and systemic symptoms, with associated exudative pleural effusions (Fig. 299-4B). Pleural involvement most often occurs 3 to 6 months after primary infection. In some cases, effusions can be large and cause dyspnea, but most often they are small and unilateral. More rarely, TB can cause an empyema when a large number of bacilli erode into the pleural space from a cavity or parenchymal focus.

Miliary TB

Miliary TB is a multisystem form of TB in which 1- to 2-mm granulomatous nodules are found in the lungs and other organ systems. The most commonly involved organs are lungs, liver, bone marrow, kidney, adrenal glands, and spleen. Miliary TB usually presents with systemic symptoms (including fever, weight loss, and night sweats), often in the absence of localizing symptoms. The physical examination also may reveal choroidal tubercles (white-yellow plaques on fundoscopic exam), lymphadenopathy, and hepatomegaly. Chest radiographic abnormalities may initially be subtle, with the classic miliary pattern seen in about 85% of patients (Fig. 299-6). Patients also may have other chest radiographic abnormalities, such as cavities, pleural effusions, or pericardial effusions. Since HIV-infected patients and patients who are being treated with TNF-α inhibitors may not form well-circumscribed granulomas, their findings on plain chest radiography may be absent or subtle, and a CT scan is more sensitive. In 20 to 40% of patients with advanced AIDS and miliary TB, blood cultures are positive for *M. tuberculosis*.

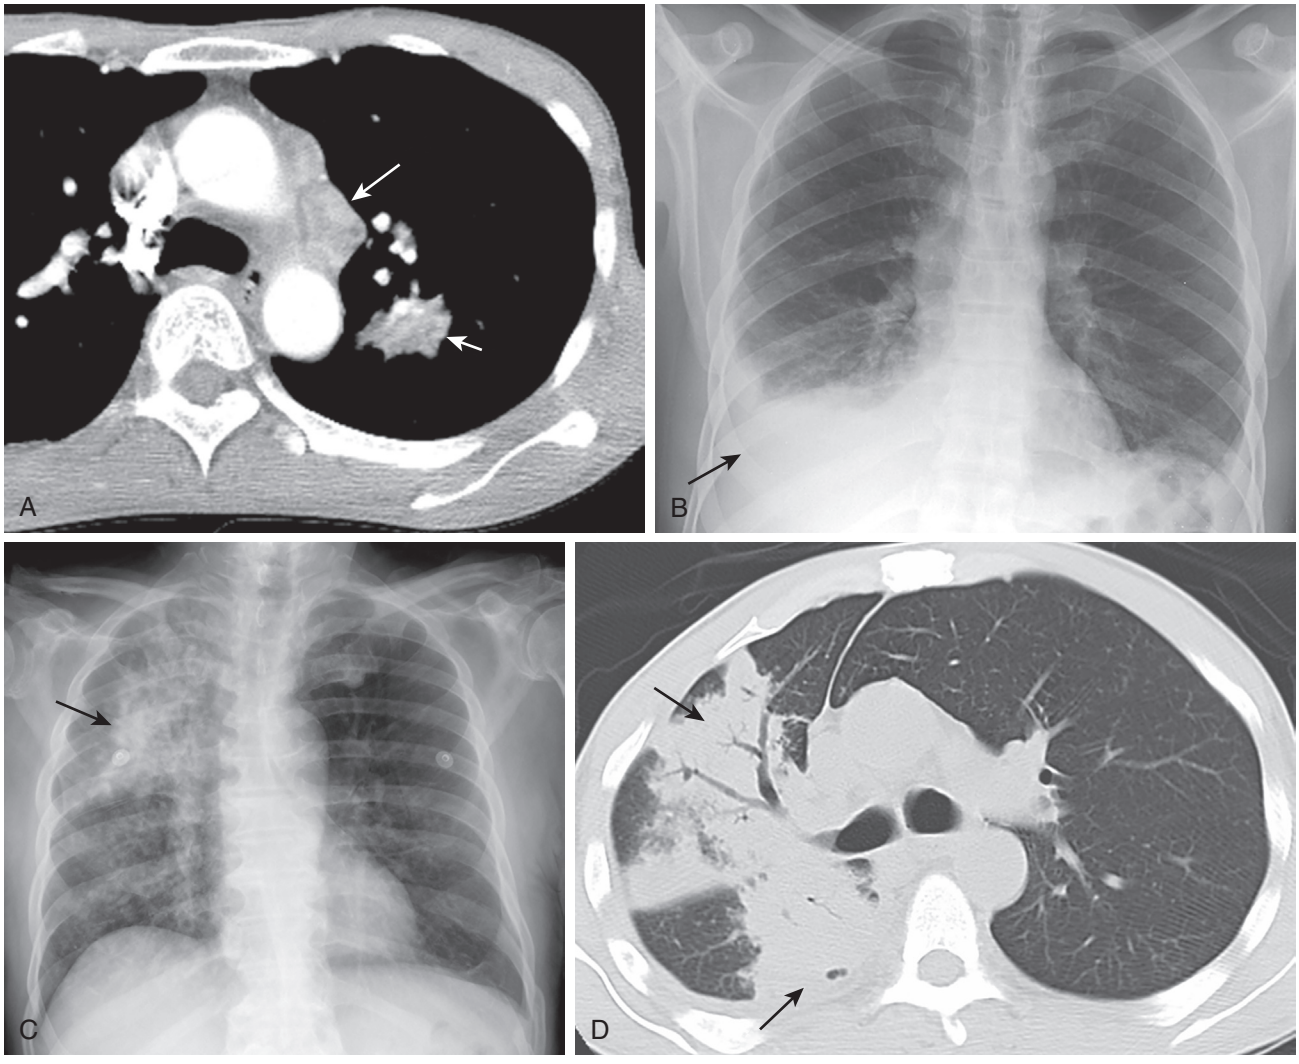


FIGURE 299-4. Radiographic images of primary and progressive primary tuberculosis (TB). A, Ghon focus in a 33-year-old woman. Chest computed tomographic image at the level of the aortopulmonary window shows the left-sided focal parenchymal opacity *(short arrow)* with ipsilateral lymphadenopathy *(long arrow)*. **B,** Chest radiograph (CXR) shows an ill-defined right lower lobe opacity with an ipsilateral pleural effusion *(arrow)* in a patient with primary TB. **C** and **D,** TB pneumonia in a 46-year-old man with progressive primary TB. **C,** Multiple opacities with dense airspace consolidation in the right upper lobe are seen on CXR. **D,** Noncontrast CT shows air bronchograms in the right upper and lower low lobes *(arrows)*. (Adapted from Restropo CS, et al. Imaging manifestations of thoracic tuberculosis, *Radiologic Clinics of North America*, 2016; 54; 453-473, an Elsevier journal.)

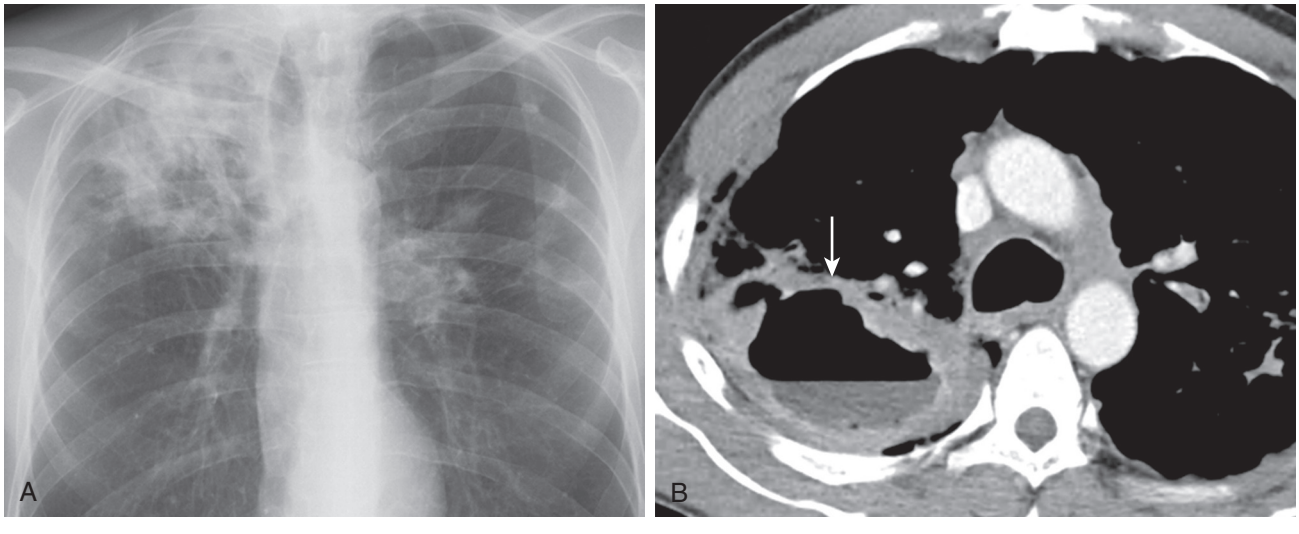

FIGURE 299-5. Cavitary tuberculosis. A, Chest radiograph shows an area of cavitation with an extensive opacity in the right upper lobe in a patient who also has left-sided nodular opacities and left hilar lymphadenopathy. **B,** Contrast-enhanced CT axial image shows the irregular cavity with an air-fluid level in the posterior right upper lobe *(arrow)*. (From Restropo CS, et al. Imaging manifestations of thoracic tuberculosis, *Radiologic Clinics of North America*, 2016; 54; 453-473.)

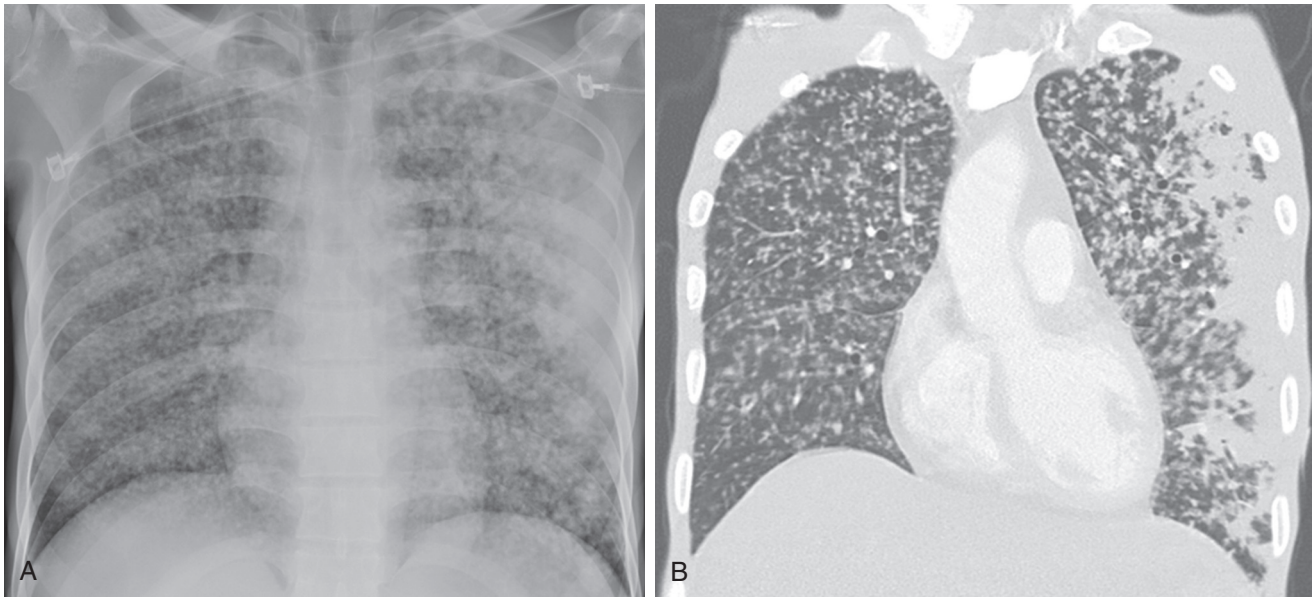

FIGURE 299-6. Miliary tuberculosis (TB). Miliary TB in a 33-year-old man. (A) Chest radiograph and (B) coronal chest computed tomographic image demonstrate very extensive micronodular disease in the bilateral lung with more confluent disease and consolidation in the periphery of the lung. (From Restropo CS, et al. Imaging manifestations of thoracic tuberculosis, *Radiologic Clinics of North America*, 2016; 54; 453-473.)

Central Nervous System TB

Central nervous system involvement with *M. tuberculosis* can manifest as a rapidly fatal meningitis or a slowly growing focal tuberculoma. TB meningitis (Chapter 381) can occur owing to meningeal seeding from a hematogenous source or rupture of a parameningeal focus into the subarachnoid space. HIV infection is the major epidemiologic risk factor for developing TB meningitis.[14] Patients with TB meningitis present with fever, headache, and neck stiffness. Cranial nerves can be involved, and the level of consciousness may be decreased. The time between the onset of symptoms and clinical presentation ranges from 5 to 30 days. More than half of patients with TB meningitis also have pulmonary disease (often miliary) and dissemination to other extrapulmonary sites.

In contrast to the 1- to 4-week course usually associated with TB meningitis, CNS tuberculomas are generally slow-growing and result in ring-enhancing lesions on imaging. They usually cause focal findings, although occasionally they cause increased intracranial pressure without focal findings.

TB Lymphadenitis

Tuberculous lymphadenitis most often causes painless involvement of posterior cervical and supraclavicular nodes (called scrofula), but it can involve any lymph node.[15] Although the lung is the likely original portal of entry, most TB lymphadenitis occurs without coexistent clinical pulmonary disease. However, lymphadenitis is more likely to accompany pulmonary TB in individuals who are coinfected with HIV.

As the disease progresses, the lymph node may suppurate and form sinus tracts. Isolated TB lymphadenitis is more common in children and adolescents than older adults, with a slight female predominance. In the United States, scrofula is more often caused by non-tuberculous mycobacteria than TB.

A variety of secondary manifestations depend upon which lymph nodes are involved. For example, intrathoracic adenopathy can cause bronchial compression, cervical node enlargement, and upper airway obstruction, whereas intrathoracic or intraabdominal nodes can disrupt lymphatics, thereby causing chylothorax or chylous ascites.

Genitourinary TB

TB involving the genitourinary system occurs in 15 to 40% of cases of patients with extrapulmonary disease.[16] Some individuals are asymptomatic and first suspected in patients who have sterile pyuria or hematuria (Chapter 100). Patients may have mild dysuria and urinary frequency, generally without systemic symptoms. TB involvement of the genital tract in women can lead to pelvic pain, menstrual irregularities, and infertility. In men, the most common presenting symptom is a scrotal mass, but prostatitis, orchitis, and epididymitis may also occur. Progressive disease can cause more severe hematuria, flank pain, and renal failure. In genitourinary TB, CT scans can show renal cortical scarring, renal masses or cavitary lesions, papillary necrosis with calyceal and ureteral dilation, or "beading" of the ureter owing to strictures. More than 50% of patients with genitourinary TB have an abnormal chest radiograph owing to prior or concurrent lung disease.

TB Pericarditis

In immunocompetent patients, TB pericarditis (Chapter 62) usually develops slowly, thereby allowing for the accumulation of large volumes of pericardial fluid without tamponade.[17] Clinical manifestations, which can be chronic or subacute, include fever, night sweats, cough, dyspnea, orthopnea, ankle edema, and chest pain. In contrast to the more chronic process in immunocompetent individuals, TB pericarditis can develop rapidly in HIV-infected individuals, in whom it is more likely to lead to tamponade and can also involve the myocardium. Over time, constrictive pericarditis occurs owing to a fibrotic reaction.

TB Peritonitis

TB peritonitis[18] (Chapter 128) occurs when *M. tuberculosis* enters the peritoneal space from adjacent lymph nodes. Patients most often present with subacute abdominal pain, anorexia, abdominal swelling, and systemic symptoms (fevers, night sweats, weight loss), although it can also mimic an acute abdomen (Chapters 118 and 128). Patients often have underlying liver disease, usually without coexistent pulmonary disease. Intra-abdominal lymphadenopathy may be seen on a CT scan.

Intestinal Tuberculosis

TB can involve any portion of the gastrointestinal tract, but it most often involves the terminal ileum or regions distal to the terminal ileum. In addition to *M. tuberculosis*, intestinal disease may also be caused by *M. bovis* from unpasteurized dairy products.

Patients most often present with abdominal pain and gastrointestinal obstruction. They also may have fever, nausea, diarrhea, weight loss, or gastrointestinal bleeding. The disease can mimic Crohn disease (Chapter 127) or be mistaken for acute appendicitis (Chapter 128) or carcinoma (Chapter 179).

Osteoarticular Tuberculosis

TB can cause subacute synovitis or osteomyelitis in any bone or joint. Usually only one bone or joint is involved, and approximately half of patients have chest radiographic abnormalities consistent with prior or concurrent pulmonary disease. TB of the spine (Pott disease) is most common, followed by disease in the hips or knees.

Spinal TB presents with back or radicular pain, most often involving the lower thoracic and upper lumbar vertebrae. The disease starts in the subchondral region of the anterior portion of the vertebral body and typically extends to involve two adjacent vertebrae and the intervertebral disc (Fig. 299-7). Paravertebral abscesses may develop along with sinus tracts. Anterior collapse of the vertebral bodies may lead to a gibbus deformity, which can cause spinal cord compression and kyphosis.

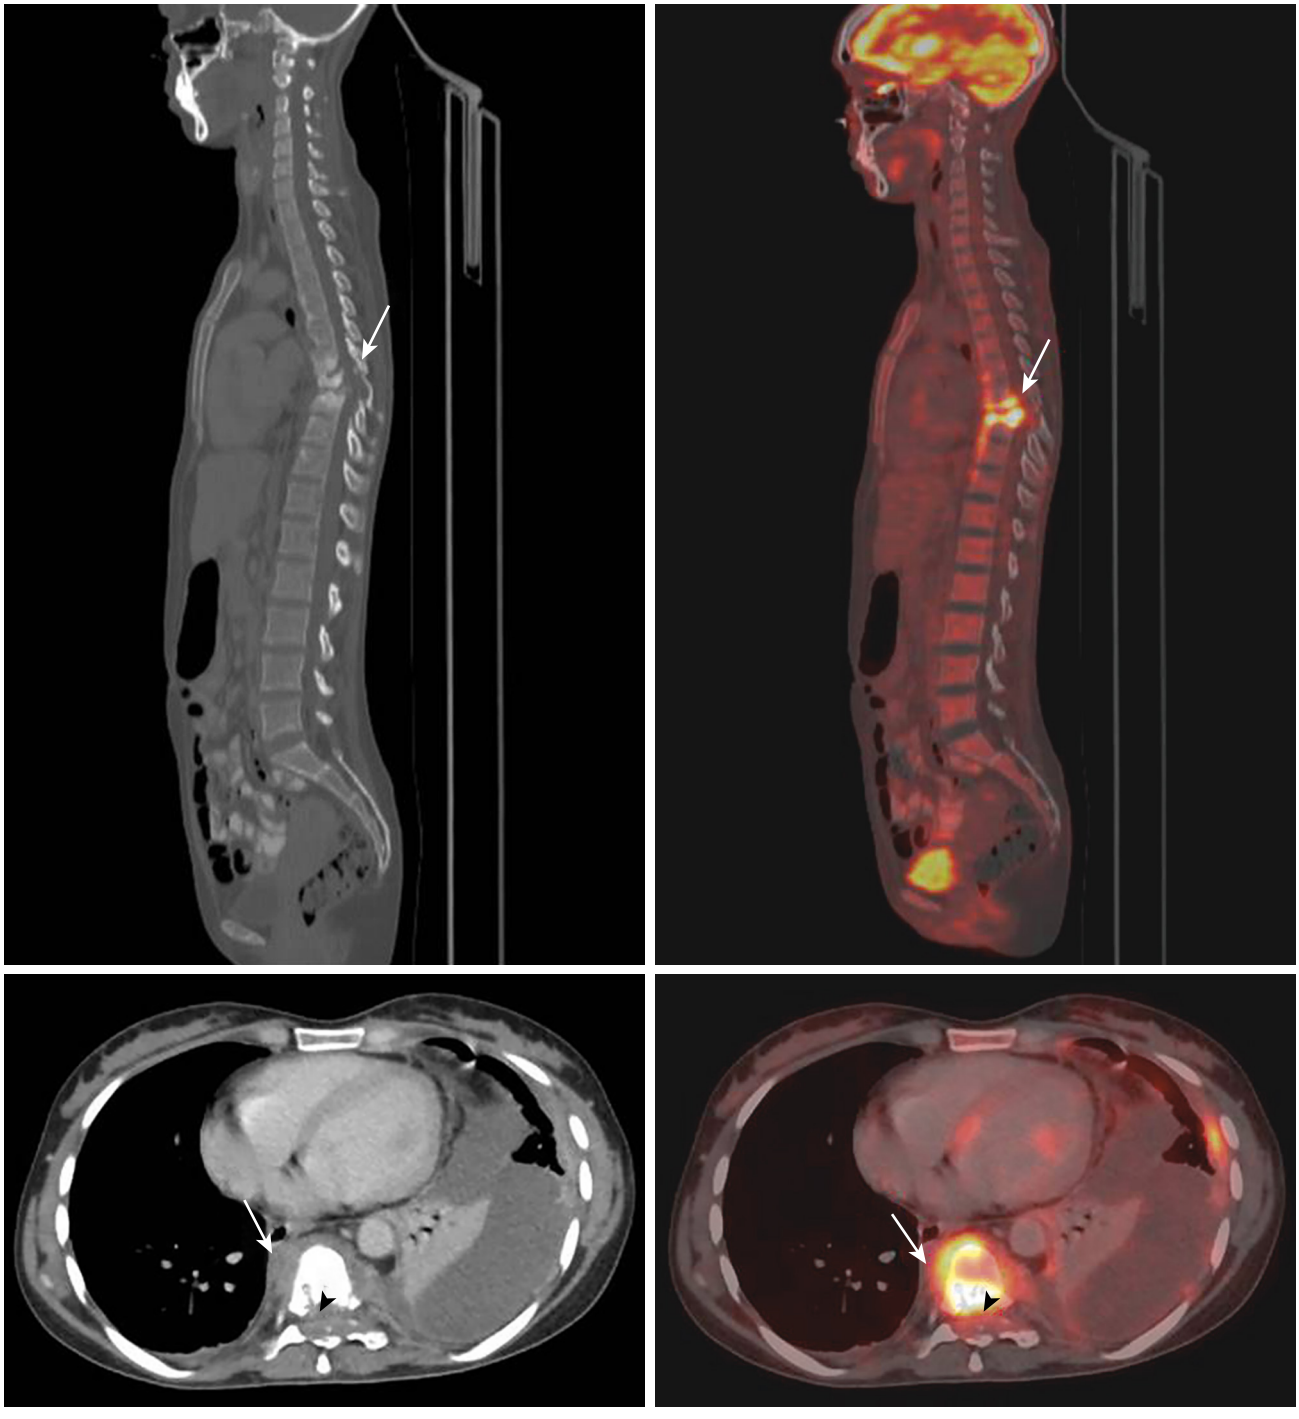

FIGURE 299-7. Pott disease. Computed tomography (CT) *(left panel)* and ^{18}F-fluorodeoxyglucose positron emission tomography (^{18}F-FDG PET)/CT-fused images *(right panel)*: transaxial and sagittal sections. Moderate to intense ^{18}F-FDG uptake is seen in a paravertebral soft tissue mass lesion extending from the level of T7–T10 vertebrae with associated lytic sclerotic changes in T7–T9 vertebrae and collapse of the T8 vertebra *(arrows)*. The lesion infiltrates into the spinal canal at the level of the T8 vertebra and involves the spinal cord *(small arrow)*. The lesion is seen to extend along the left costal margin, with faint ^{18}F-FDG uptake and foci of calcification, likely representing a cold abscess (courtesy of Prof. B.R. Mittal). (From Skoura E, Zumla A, Bomanji J. Imaging in tuberculosis. *Int J of Inf Dis*. 2015;32:87-93.)

Immunologic Manifestations of TB

Hypersensitivity reactions to mycobacterial antigens can lead to erythema nodosum and erythema induratum (see Figs. 407-24 and 407-25), both of which cause subcutaneous nodules, most often on the lower extremities. These immune-mediated cutaneous reactions (termed tuberculids) differ from cutaneous TB that is due to actual infection of the skin. When reactive arthritis occurs in conjunction with erythema nodosum, the syndrome is referred to as Poncet disease.

TB-associated immune reconstitution inflammatory syndrome (Chapter 358), which is an exuberant inflammatory response in the context of reduced immunosuppression and high burden of *M. tuberculosis* antigen, occurs in 5 to 50% of patients who are started on antiretroviral therapy for HIV (see HIV-TB coinfection, later).[19] The immune recovery can lead to a dysregulated inflammatory response against *M. tuberculosis* antigens, with either a paradoxical clinical worsening (e.g., fever, lymphadenitis) or unmasking of previously undiagnosed TB. TB-associated immune reconstitution inflammatory syndrome that involves the central nervous system is associated with a high morbidity and mortality. Paradoxical reactions after initiating appropriate TB therapy also can lead to clinical or radiologic worsening in patients without HIV.

DIAGNOSIS

Skin Testing for Latent TB Infection

Latent tuberculosis infection is defined by the absence of TB symptoms and signs, together with a positive test indicating the presence of delayed-type hypersensitivity to TB antigens. By definition, the diagnosis of latent tuberculosis infection first requires that active TB be excluded, followed by a

positive indirect test that indicates the presence of *M. tuberculosis*. In low-risk populations, most positive skin tests will be a false positive.[20] Testing for latent tuberculosis infection should be performed once to exclude latent TB and again after any potential re-exposure in persons with the following risk factors:

- Birth or residence in a country in which the incidence rate of TB is high (TB incidence >100/100,000 population/year) or medium (TB incidence 10 to 100/100,000 population/year) regardless of year of emigration. These countries include most countries in Asia, Africa, Latin America, the Pacific Islands, and Eastern Europe.
- Close contact to someone with infectious TB disease.
- Immunosuppression, current or planned, including HIV infection; organ transplantation; or treatment with a TNF-α antagonist (e.g., infliximab, etanercept, others), corticosteroids (equivalent of prednisone ≥2 mg/kg/day, or ≥15 mg/day for ≥1 month), or other immunosuppressive medication.
- Other medical conditions or social circumstances that meet criteria in state or local recommendations, such as homelessness, incarceration, or occupational risk of TB. In cases with potential ongoing exposure, annual testing may be indicated.

No gold standard determines the presence or absence of latent tuberculosis infection, so clinical judgment is required to interpret these indirect tests.

The Mantoux tuberculin skin test uses an intradermal injection of five tuberculin units of *M. tuberculosis* purified protein derivative (PPD). After 48 to 72 hours (and up to 96 hours), the width of dermal reaction reflects infiltration of host immune effector cells. Cut points define a positive test based upon the prior probability of infection and the likelihood of progression to active TB if infected (see Table 299-1).

The tuberculin skin test is highly dependent upon appropriate storage, correct administration, and accurate interpretation. The response to the test can also be nonspecific: a positive response may reflect exposure to nontuberculous mycobacteria or to prior bacille Calmette-Guérin (BCG) vaccination rather than to *M. tuberculosis* infection. Given these limitations, the interferon-gamma release assay (IGRA), described later, is the test of choice in persons with a history of BCG vaccination. A confirmatory IGRA should be performed if a patient has a positive tuberculin skin test result without any known risk for TB exposure or has a history of BCG vaccination. Response to the tuberculin skin test wanes over time, so a positive reaction may disappear by 10 years after infection but may reappear after being "boosted" by a PPD/tuberculin skin test or by exposure to environmental nontuberculous mycobacterial antigens. A boosted PPD/tuberculin skin test response is not a false-positive response, but it does not reflect recent TB infection. If individuals undergo serial PPD/tuberculin skin tests, such as employees in health care settings, a two-step approach should be used for first-time testing: if the initial test is negative, a second test administered at least a week after the first test to unmask a waned tuberculin skin test response. Because the booster phenomenon may last a year or more, failure to perform a two-step test in initial testing may give the false impression that an individual with a positive test on a subsequent annual test has acquired TB infection in the interim. When individuals are tested serially, a positive test (or tuberculin skin test "conversion") is defined by induration that increases by at least 6 mm compared with prior testing and results in 10 mm or greater induration. True skin test conversion within a 2-year period implies recent infection and is a significant risk factor for progression to TB.

IGRA blood testing is generally preferred over the tuberculin skin test for the diagnosis of latent tuberculosis infection.[21] Two assays are licensed in the United States: the QuantiFERON-TB Gold Plus (QFT-G+) and the T-SPOT.*TB* (Tspot). Both tests measure the amount of IFN-γ released by T lymphocytes in response to exposure to TB-specific antigens. These antigens are not present in BCG or most nontuberculous mycobacteria (exceptions include *Mycobacterium kansasii*, *Mycobacterium marinum*, *Mycobacterium gordonae*, and *Mycobacterium szulgai*), so these tests are much more specific than the tuberculin skin test, and they should be used in persons with a history of BCG vaccination. Other advantages of the IGRAs include objective measures of response that are not subject to inter-rater measurement variability and the lack of need for a return visit to measure the response. Disadvantages include cost and, in some instances, the reproducibility of the results. The QFT-G+ is an enzyme-linked immunosorbent assay (ELISA)–based test that is considered positive if the result is ≥0.35 IU/mL. However, a significant number of individuals with results just above this threshold will subsequently have a negative test, so current recommendations suggest repeat testing in a person with a positive result if the prior probability for a positive test is low. Repeat testing is also recommended for indeterminate QFT-G+ or invalid Tspot results, which reflect the failure of a positive or negative control in the test.

Testing with both a Mantoux tuberculin skin test and an IGRA is warranted in persons who are both at high epidemiologic risk of TB infection (e.g., household contact of recently diagnosed person with pulmonary TB) and at high risk for progression to active TB if infected (e.g., poorly controlled HIV). If either the PPD/tuberculin skin test or the IGRA is positive, treatment for latent tuberculosis infection is indicated. PPD/tuberculin skin test may be preferred in household contact investigations because it may turn positive earlier than an IGRA. In some instances, treatment for latent tuberculosis infection may be warranted despite a negative tuberculin skin test and IGRA, for example, in a person with poorly controlled HIV who resides in a household where there is evidence for household transmission or in a person with poorly controlled HIV who lives in a country with a high TB burden.

The sensitivity of these tests is reduced in immunocompromised persons, persons with sarcoidosis, after live virus vaccination, and in persons with active TB. In instances in which both a measles/mumps/rubella vaccination and a TB test are indicated, both may be administered simultaneously. However, if a live virus vaccine has already been given more than 1 day prior, at least 28 days should elapse before administering the PPD/tuberculin skin test or IGRA. These tests cannot be used to exclude or establish a diagnosis of active TB. In addition, both the tuberculin skin test and IGRA tests typically remain positive despite treatment for latent tuberculosis infection, although their degree of positivity may wane over time. Treated and untreated patients should be instructed that no further testing for latent tuberculosis infection is indicated because no change in the results is expected.

Active Tuberculosis

In countries with limited resources and a high burden of TB, the diagnosis of active TB may be based solely upon typical clinical symptoms and signs, with or without sputum microscopy. All persons with TB should be tested for HIV because of its strong epidemiologic association with TB.

An empiric treatment approach has the advantage of early treatment of persons who are at high risk of rapid progression of disease, such as individuals with advanced HIV disease, but it also leads to overdiagnosing and overtreating TB, as well as failing to detect drug resistance. In higher-resource settings, empiric TB treatment, if required, should be done in concert with procedures to confirm the diagnosis and characterize drug susceptibility. In some cases, particularly in patients with paucibacillary disease in which the number of organisms is small in clinical specimens (e.g., extrapulmonary TB), observing an appropriate response to standard TB therapy while excluding alternative diagnoses may be the only way to confirm TB.

Pulmonary TB

The diagnosis of pulmonary TB begins with a careful history and clinical suspicion. Patients with pulmonary TB typically have had symptoms for weeks to months. Although patients may minimize these symptoms, they are usually more than sufficient to warrant radiographic imaging, which usually shows pulmonary infiltrates (see Figs. 299-4 and 299-5). A misdiagnosis of community-acquired pneumonia (Chapter 85) may lead to inappropriate treatment with one of the respiratory quinolones, which have activity against TB and can provide transient clinical improvement and delay the correct diagnosis. These errors are more common in low-prevalence areas, where experience in the diagnosis of TB is limited.

When pulmonary TB is suspected, sputa should be collected for microscopic examination, culture, and PCR testing. Three sputum specimens should be collected at least 8 hours apart, with two of them collected in the morning on separate days. Sputum induction with aerosolized saline increases the yield. The gold standard for diagnosis is growth of *M. tuberculosis* in culture, typically within 1 to 3 weeks by modern testing methods. PCR testing and direct microscopic examination can yield a diagnosis more quickly, but they are less sensitive than culture. Fluorochrome stains, which are standard in clinical TB laboratories, are more sensitive for detecting *M. tuberculosis* than classical AFB stains, but approximately 50% of patients with pulmonary TB are sputum smear negative. DNA amplification testing by GenXpert MTB/RIF, which is more than 95% sensitive and specific in diagnosing TB from smear-positive sputum, can rapidly confirm the diagnosis of TB and detect the presence of *rpoB* mutations that confer rifampin resistance, which is strongly correlated with multidrug-resistant TB. When the clinical suspicion is high, it is worthwhile to perform PCR testing on three smear-negative specimens, for which its sensitivity is approximately 70%. If TB is not confirmed by direct testing of sputa using DNA amplification, *M. tuberculosis* can be confirmed by testing with DNA probes or other methods as soon as growth is detected in selective mycobacterial media.

Lipoarabinomannan, a glycolipid of the *M. tuberculosis* cell wall, can be detected in the urine of patients with pulmonary or extrapulmonary TB and advanced HIV, but this test is not available in the United States. In patients who are from high-prevalence countries and who are unable to produce sputum, a gastric aspirate for AFB smear and TB DNA testing is a potential option.

Although the majority of patients with pulmonary TB can be diagnosed by noninvasive means, bronchoscopy with bronchoalveolar lavage may be required to diagnose TB or make an alternative diagnosis, particularly in severely ill or immunocompromised patients in whom diagnostic delays may lead to poor outcomes. In many cases, the diagnosis rests on the clinical and radiographic response to therapy in the appropriate epidemiologic setting.

Extrapulmonary TB

Extrapulmonary TB often presents a diagnostic challenge. As with pulmonary TB, an index of suspicion is required to maximize the likelihood for making a diagnosis. The number of organisms in an extrapulmonary specimen is smaller than in pulmonary TB, so negative AFB stains and cultures are common. Furthermore, if a tissue is biopsied and infection is not initially considered, the sample may be placed in formalin and not submitted to the microbiology laboratory. PCR for TB can be performed by reference laboratories on fixed tissue, but the sensitivity is lower than with culture, particularly for specimens that stain negatively for AFB.

AFB stains, cultures, and TB DNA amplification should be performed on normally sterile fluids in persons with suspected TB. The yield of AFB stains and culture on these fluids is lower than in tissue, so large volumes should be submitted.

The cerebrospinal fluid (CSF) in TB meningitis may show a predominance of neutrophils but classically shows a lymphocytic CSF pleocytosis (although polymorphonuclear leukocytes may also predominate), with a low glucose level and a modestly elevated protein level. Rarely, TB meningitis may be eosinophilic (Chapter 381). A magnetic resonance imaging (MRI) scan of the head can show contrast enhancement of the basilar meninges, infarctions, hydrocephalus, and focal inflammatory lesions (tuberculomas).

For TB adenitis, lymph node biopsy or aspirations will typically show granulomas (except in patients who are on TNF inhibitors), with or without acid-fast organisms, and cultures are positive in approximately 70% of cases. Infected pleural (Chapter 86), pericardial (Chapter 62), and peritoneal (Chapter 128) fluids are exudative with a low glucose level and a lymphocytic predominance. Pleural effusions or ascites caused by TB may be chylous.

In pleural TB, the pleural fluid is often paucibacillary, so a pleural biopsy may be needed to diagnose TB pleuritis. In TB empyema, smears and cultures of the pleural fluid are usually positive, thereby making pleural biopsy unnecessary.

In TB peritonitis, ascitic fluid is most often exudative, and it is commonly negative for acid-fast bacilli on smear and culture. The highest diagnostic yield is achieved with peritoneal biopsy. For intestinal TB (due to either *M. tuberculosis* or *M. bovis*), histopathology and culture are used to establish the diagnosis. TB involving the genitourinary tract is suggested by sterile pyuria and can be diagnosed by culturing an early morning urine sample specifically for mycobacteria.

TB pericardial effusions (Chapter 62) may be massive and hemorrhagic. Malignancy, empyema, and rheumatologic disorders may also result in exudative effusions with low glucose levels. In TB pericarditis, *M. tuberculosis* can often be cultured from the fluid, although pericardial biopsy is more sensitive.

The possibility of nontuberculous mycobacteria (Chapter 300) should be considered in appropriate clinical circumstances, as should other infectious agents that may result in granulomas with negative AFB stains, including, but not limited to, endemic fungal infections (Chapter 308), cryptococcus (Chapter 309), bartonella (Chapter 291), and coxiella (Chapter 302). Noninfectious causes of granulomatous inflammation in various tissues include sarcoidosis (Chapter 83), Crohn disease (Chapter 127), lymphoma, and granulomatosis with polyangiitis (Chapter 249).

TREATMENT

Latent TB Infection

Treatment of latent TB infection reduces the lifetime risk of active TB by 75 to 90%, depending on adherence to treatment.[22] Three rifamycin-based regimens are preferred over two alternative isoniazid-based regimens (Table 299-2 and https://www.cdc.gov/tb/topic/treatment/ltbi.htm), because the former require shorter durations of therapy.

The strongly recommended regimen is 3 months of rifapentine plus isoniazid given weekly for 12 doses to adults, including patients with HIV infection, unless there are contraindicated drug interactions.[23] Directly observed therapy (DOT), whereby a health care provider or another designee watches a person with TB take each dose, assists with adherence to therapy and detection of adverse drug events. When administered by directly observed therapy, this regimen is as effective as 9 months of daily isoniazid, with superior completion rates (despite higher rates of discontinuation due to side effects) and less hepatotoxicity in HIV-negative patients.[A1] The completion rate for self-administered therapy is inferior to the completion rate with directly observed therapy, except in the United States.[A2] Disadvantages of this regimen include cost, particularly if provided by direct observation, pill burden, and a 1 per 1000 persons risk of hypotension and syncope severe enough to require hospitalization but not to cause death. The second preferred regimen is 4 months of daily rifampin, which is appropriate for HIV-negative adults but without sufficient evidence to recommend it in HIV-positive patients. It is equivalent in effectiveness, has higher rates of completion, and is less toxic than 9 months of isoniazid.[A3] The primary disadvantage of this regimen is drug-drug interaction with many medications, including but not limited to methadone, hormonal contraceptives, azole antifungals, and warfarin. Rifabutin has fewer drug interactions and may be used in some cases when rifampin is contraindicated. The third preferred regimen is 3 months of rifampin plus isoniazid for adults, including HIV-positive patients, barring contraindicated drug interactions. It appears to have similar effectiveness and risks of toxicity compared with 6 months of isoniazid.

Six months of daily isoniazid is an alternative regimen that is highly effective for HIV-negative adults and conditionally recommended for HIV-positive adults. Among HIV-positive persons living in an area with a high incidence of TB, 6 months of daily isoniazid is complementary to antiretroviral therapy in preventing TB disease regardless of IGRA results. Nine months of isoniazid is an alternative regimen for adults who are HIV-positive or HIV-negative. When isoniazid is prescribed, pyridoxine (25 to 50 mg daily) should be administered to prevent peripheral neuropathy. Baseline liver tests should be obtained in patients who are over age 35 years, are infected with HIV, or have underlying liver disease or significant alcohol use. Laboratory monitoring (see Drug Monitoring, later) for potential drug toxicity is recommended only in patients who have symptoms or signs suggestive of toxicity.

Active Pulmonary Tuberculosis

All patients who have active TB should be managed by or with the guidance of an experienced TB clinician. Within the United States, expertise is available through the National TB Centers of Excellence. Outside the United States, expertise can be obtained through groups such as the Global TB Network, a working group within the World Association for Infectious Diseases and Immunological Disorders (http://www.waidid.org/site/workinggroups).

All TB patients should have their isolates tested for drug susceptibility. Molecular methods enable rapid identification of TB in appropriate specimens and identify drug-resistant TB. Commercially available molecular technology (Xpert MTB/RIF) simultaneously detects *M. tuberculosis* DNA and the presence of rifampin-resistance mutations. Substantial data can guide the choice of drug regimens for patients with drug-susceptible TB or drug-resistant TB, as well as how to screen for potential adverse events and manage any that occur. For example, resistance to rifampin strongly correlates with multidrug-resistant TB.

Treatment of persons with TB serves the dual role of curing the disease in the individual and preventing its spread to others. In the United States, most treatment is provided in public health clinics or academic centers under the guidance of the four regionally assigned TB Centers of Excellence, which cover all 50 states and U.S. territories (https://www.cdc.gov/tb/education/tb_coe/default.htm).

Patients who have pulmonary TB are considered infectious until they have had at least 2 weeks of therapy, show a clinical response (e.g., reduced cough, weight gain, resolution of fever and night sweats), and have no detectable acid-fast bacilli by microscopy on three sputum specimens at least 8 hours apart. Patients may be discharged from the hospital prior to being noninfectious if they are tolerating TB therapy and are going to their own homes or to facilities with proper isolation rooms, provided that the clinicians have notified the appropriate health department, verified contact information, and have a follow-up plan in place.

Follow-up must include monthly visits for clinical assessment and examination of sputum until the sputum is negative on at least two consecutive cultures. By 2 months after the start of therapy, about 75 to 80% of patients with pulmonary TB will be sputum culture negative, and about 95% will be negative after 3 months. If the sputum culture is persistently positive at 3 months, causes include nonadherence, low therapeutic drug levels, an alternative or complicating diagnosis, and unrecognized or emerging drug resistance. A positive sputum culture at 4 months defines treatment failure, which is rare in properly treated drug-sensitive disease and should prompt expert guidance and more complex treatment options. A single drug should never be added to a failing TB regimen, since this approach promotes further resistance.

Treatment of active TB requires multidrug therapy to prevent the selection of resistant organisms.[24] In drug-susceptible pulmonary TB, an initial four-drug intensive phase for 8 weeks is followed by a two-drug continuation phase for 4 to 6 months (Tables 299-3, 299-4, and 299-5). Rifampin (or rifabutin in selected patients who are intolerant to rifampin or in whom it risks drug-drug interactions), isoniazid, pyrazinamide, and ethambutol comprise the intensive phase,

TABLE 299-2 ADULT ORAL DOSES FOR TREATMENT OF LATENT TUBERCULOSIS INFECTION TREATMENT REGIMENS

DRUG	DURATION	DOSE PER KG BODY WEIGHT	FREQUENCY	TOTAL DOSES
PREFERENCE ROUTINES				
1. Isoniazid* and rifapentine†	3 mo	Isoniazid: 15 mg/kg rounded up to the nearest 50 or 100 mg (maximum dose 900 mg) Rifapentine: 25.1-32.0 kg 600 mg 32.1-49.9 kg 750 mg ≥50.0 kg 900 mg (maximum dose)	Once weekly	12
2. Rifampin‡	4 mo	10 mg/kg (maximum dose 600 mg)	Daily	120
3. Isoniazid* and rifampin‡	3 mo	Isoniazid*: 5 mg/kg (maximum dose 300 mg) Rifampin‡: 10 mg/kg (maximum dose 600 mg)	Daily	90
4. Isoniazid*	6 mo	5 mg/kg (maximum dose 300 mg)	Daily	180
		15 mg/kg (maximum dose 900 mg)	Twice weekly§	52
5. Isoniazid	9 mo	5 mg/kg (maximum dose 300 mg)	Daily	270
		15 mg/kg (maximum dose 900 mg)	Twice weekly§	76

*Isoniazid is formulated as 100-mg and 300-mg tablets. Note: pyridoxine (vitamin B_6), 25 to 50 mg/day, is given with isoniazid to all persons at risk of neuropathy.
†Rifapentine is formulated as 150-mg tablets in blister packs that should be kept sealed until use.
‡Rifampin (rifampicin) is formulated as 150-mg and 300-mg capsules.
§Must be provided by directly observed therapy (i.e., a health care worker observes the ingestion of medication).

TABLE 299-3 TREATMENT OF DRUG-SUSCEPTIBLE PULMONARY TUBERCULOSIS (SEE TABLES 299-4, 299-5, AND 299-6 FOR DOSING)

	INTENSIVE PHASE		*CONTINUATION PHASE*			
REGIMEN	**DRUG***	**INTERVAL AND DOSE* (MINIMUM DURATION)**	**DRUGS**	**INTERVAL AND DOSE* (MINIMUM DURATION)†**	**COMMENTS‡**	**REGIMEN EFFECTIVENESS**
1	Isoniazid Rifampin Pyrazinamide Ethambutol	5 or 7 days/week for 8 weeks	Isoniazid Rifampin	5 or 7 days/week for 18 weeks	Preferred for newly diagnosed pulmonary tuberculosis	Greater
2	Isoniazid Rifampin Pyrazinamide Ethambutol	5 or 7 days/week for 8 weeks	Isoniazid Rifampin	3 times weekly for 18 weeks	Preferred alternative when more frequent DOT is difficult to achieve	
3	Isoniazid Rifampin Pyrazinamide Ethambutol	3 times weekly for 8 weeks	Isoniazid Rifampin	3 times weekly for 18 weeks	Missed doses can lead to treatment failure, relapse, and acquired drug resistance, especially in patients with HIV and/or cavitary disease	
4	Isoniazid Rifampin Pyrazinamide Ethambutol	7 days/week for 2 weeks, then twice weekly for 6 weeks	Isoniazid Rifampin	Twice weekly for 36 doses (18 weeks)	Do not use twice-weekly regimens in HIV-infected patients or patients with smear-positive and/or cavitary disease	Lesser

*When DOT is used, drugs may be given 5 days per week. DOT should be used when drugs are administered <7 days per week.
†Patients with cavitary disease and positive cultures at completion of 2 months of therapy should receive a 7-month continuation phase.
‡Pyridoxine (vitamin B_6), 25-50 mg/day, is given with isoniazid to all persons at risk of neuropathy (e.g., pregnant women; persons with human immunodeficiency virus; patients with diabetes, alcoholism, malnutrition, or chronic renal failure; or patients with advanced age). For patients with a pre-existing peripheral neuropathy, the pyridoxine dose should be increased to 100 mg/day.
DOT = directly observed therapy; HIV = human immunodeficiency virus.

Thrice weekly (mg/kg)	1200 mg (21.8-30.0)	2000 mg (26.7-35.7)	2400 mg (26.7-31.6)
Twice weekly (mg/kg)	2000 mg (36.4-50.0)	2800 mg (37.3-50.0)	4000 mg (44.4-52.6)

*Based on estimated lean body weight. Optimal doses for obese patients are not established.
†Numbers in parentheses are the calculated mg/kg doses for patients at the highest and lowest body weights in the weight band.

which should be followed by rifampin and isoniazid in the continuation phase. Ethambutol can be discontinued if drug susceptibility studies demonstrate that the patient's isolate is sensitive to both isoniazid and rifampin. The precise duration of the continuation phase is determined by the presence or absence of cavitary disease and the rapidity of the microbiologic response to therapy. For nonresistant TB infection, 4 months of therapy with rifapentine, moxifloxacin, isoniazid, and pyrazinamide might be as good as 6 months of four-drug therapy with rifampin, isoniazid, pyrazinamide, and ethambutol[A4]; however, both groups in that study had high rates of unfavorable outcomes, so further studies will be required to recommend this shorter regimen. Vitamin B_6 (pyridoxine) supplementation often is used in all patients but is especially recommended in patients who are at risk for isoniazid-induced peripheral neuropathy (e.g., pregnant women, elderly patients, or patients with HIV, diabetes, alcoholism, malnutrition, or chronic renal failure). For patients with peripheral neuropathy, experts recommend the pyridoxine dose should be 100 mg/day. Some experts substitute linezolid (600 mg daily),[A5] moxifloxacin (400 mg orally daily), or levofloxacin (750 mg orally daily) for ethambutol during the intensive phase when ethambutol is contraindicated or instead of isoniazid throughout treatment in adults in whom isoniazid cannot be used because of side effects or resistance to it. Inclusion of pyrazinamide in the intensive phase of therapy allows completion of therapy after 26 weeks in persons whose sputum cultures convert to negative within 2 months of initiating treatment. For patients who are unable to tolerate pyrazinamide, similar outcomes are achieved with a 9-month regimen of isoniazid plus rifampin. Shorter courses of therapy using bedaquiline/linezolid plus isoniazid, pyrazinamide, and ethambutol have shown promising results in patients who have rifampin-susceptible TB.[A6]

Directly observed therapy, which is considered the standard of care for treatment of tuberculosis in the United States, is provided daily 5 days a week, with or without self-administered therapy on weekend days, preferably for the duration of therapy. Alternative administration schedules risk higher rates of relapse, but directly observed therapy administered three times weekly can be considered for the continuation phase in situations in which more frequent directly observed therapy is difficult to achieve; however, this schedule should be used with caution in patients who have HIV or cavitary disease. Twice-weekly regimens are generally discouraged. Daily electronic directly observed therapy using a secure connection is a suitable alternative to intermittent in-person directly observed therapy in patients who can use this technology (https://www.cdc.gov/tb/publications/pdf/tbedottoolkit.pdf). Multifaceted, patient-centered treatment strategies using enablers to remove economic barriers to treatment and incentives (food or cash) should be incorporated in case management programs to facilitate adherence and to promote patient satisfaction.

Drug Monitoring

Monitoring of therapeutic drug levels should be considered for patients who respond poorly to therapy, obese or frail patients, and patients who have HIV, severe renal insufficiency, or conditions associated with impaired drug absorption. Routine periodic laboratory monitoring is not required but is indicated for patients who report new fever, nausea, vomiting, abdominal pain, or unexplained weight loss, as well as for patients who may be unable or less likely to report these symptoms owing to language, cultural, or other barriers. Persons with TB should be carefully instructed to report these symptoms, and directly observed therapy personnel should be trained to inquire about and to document them systematically. Therapy should be interrupted if the alanine aminotransferase (ALT) level is 3 times or more the upper limit of normal in the presence of gastrointestinal symptoms or 5 times or more the upper of limit of normal in the absence of symptoms. Other causes of elevated aminotransferase levels should be sought (e.g., viral hepatitis [Chapter 134 and 135], biliary disease [Chapter 141], alcohol use [Chapter 138], and other hepatoxic prescription or over-the-counter drugs or supplements [Chapter 136]). The optimal approach to reintroduction of TB treatment is unknown and requires clinical judgment by a TB expert.

Extrapulmonary TB

Most patients with drug-sensitive extrapulmonary TB can be managed with standard 6- to 9-month therapy. Nine- to 12-month therapy is recommended for scrofula and for miliary, meningeal, bone, joint, genitourinary, gastrointestinal, or spinal TB. Surgical débridement may be required for bone or spinal TB. Adjunctive corticosteroids (e.g., dexamethasone 0.4 mg/kg/day for 7 days then 0.3 mg/kg/day for 7 days, then 0.2 mg/kg/day for 7 days, then 0.1 mg/kg/day for 7 days, then 4 mg/day for 7 days, and then tapered off by 1 mg/day each week) confer a mortality benefit in both HIV-negative and HIV-positive persons with TB meningitis (Chapter 381).[25] Clinical worsening may require that doses be increased or tapered more slowly. However, corticosteroids have no proven benefit for TB at other sites. Shunting may be required for TB-related hydrocephalus.

HIV-TB Coinfection

All persons with TB should be tested for HIV because of its strong epidemiologic association with TB. For TB-infected HIV patients who are not yet on antiretroviral therapy and have CD4 counts less than 50 cells/μL, antiretroviral therapy (Chapter 357) should be initiated within 2 weeks after TB therapy has begun, except a 2-week delay is recommended in patients with TB meningitis. For HIV-infected persons who have no overt evidence of TB, have low CD4 counts (<100/μL), and live in high-burden countries, empiric TB treatment is not superior to TB screening and targeted treatment and results in more side effects.[A7] Patients with low CD4 counts are at higher risk of TB-immune reconstitution inflammatory syndrome (Chapter 358) when antiretroviral therapy is initiated early than are patients with higher CD4 counts, but the mortality benefit from early antiretroviral therapy outweighs this risk. TB-immune reconstitution inflammatory syndrome, which is associated with apparent, paradoxical worsening of TB owing to inflammation associated with immune reconstitution, generally occurs 2 to 8 weeks after initiating antiretroviral therapy. The initiation of antiretroviral therapy also can unmask underlying TB when undiagnosed TB becomes clinically evident with immune reconstitution. For patients with CD4 counts 50/μL or higher, antiretroviral therapy should be started no later than 8 to 12 weeks after initial TB treatment.

For patients whose HIV is already being treated with antiretroviral therapy, standard daily 6-month TB therapy results in cure rates that are comparable to non–HIV-infected persons. Daily regimens reduce the risk of relapse compared with intermittent regimens, which are not recommended. For HIV-infected persons who have not been taking antiretroviral therapy, a continuation phase of 7 months is recommended (for a total of 9 months of therapy). A 7- to 10-month continuation phase is also recommended for patients who have cavitary disease and still have positive cultures at 2 months, as well as patients who have TB meningitis or TB of the bone, joint, or spine.

Because of the risk of significant drug-drug interactions (e.g., rifamycins with antiretroviral therapy owing to induction of hepatic CYP3A and the transporter P-glycoprotein), concomitant antiretroviral therapy and TB therapy are best managed by clinicians familiar with HIV, TB, and these interactions.[26] A practical, well-tolerated option to treat TB in suitable drug-susceptible patients substitutes standard-dose rifabutin for rifampin and uses an antiretroviral therapy approach composed of once-daily dolutegravir, once-daily tenofovir disoproxil fumarate, and emtricitabine. Rifampin may be used without dose adjustment with efavirenz-based regimens and adjusted to twice daily with dolutegravir-based regimens. Half-dose rifabutin may be used with ritonavir-boosted protease inhibitors, but nonadherence to this HIV treatment can result in subtherapeutic levels of rifabutin, thereby leading to rifamycin resistance. Tenofovir alafenamide–containing regimens are not recommended with either rifampin or rifabutin.

Drug-Resistant Tuberculosis

Monoresistance to isoniazid has no effect on the outcome of treatment when identified early and addressed appropriately. For patients with isoniazid-monoresistant TB, the isoniazid should be discontinued and replaced with moxifloxacin (400 mg daily orally) or levofloxacin (750 mg daily orally), if susceptible, as part of a 6-month regimen that also includes daily rifampin, ethambutol, and pyrazinamide.[A8] The duration of pyrazinamide can be shortened to 8 weeks for patients who have noncavitary pulmonary or extrapulmonary disease. If the organism is not sensitive to a fluoroquinolone, expert consultation is required. *M. tuberculosis* that is monoresistant to rifampin can also be treated successfully with oral antibiotics.[A9,A10]

Multidrug-resistant TB, which is defined by resistance to at least isoniazid and rifampin, requires the assistance of an expert in the treatment of

TABLE 299-6 DOSING RECOMMENDATIONS FOR ADULTS WITH CREATININE CLEARANCE <30 ML/MIN OR RECEIVING HEMODIALYSIS

DRUG	RECOMMENDED DOSE AND FREQUENCY
Isoniazid	300 mg once daily or 900 mg 3 times/week
Rifampin	600 mg once daily or 600 mg 3 times/week
Pyrazinamide	25-35 mg/kg 3 times/week
Ethambutol	20-25 mg/kg 3 times/week

Medications should be given after dialysis on the day of dialysis.
Monitoring of serum drug concentrations should be considered to ensure adequate drug levels and to avoid toxicity.
Based on estimated lean body weight. Optimal doses for obese patients are not established.

multidrug-resistant TB.[27,28] Failure to recognize and properly treat multidrug-resistant TB is associated with poor outcomes. An all-oral regimen is possible, as determined by drug susceptibility testing: five active drugs for a 5- to 7-month intensive phase, followed by four active drugs in the continuation phase that continues for a total treatment duration of between 15 and 21 months under expert guidance after cultures convert from positive to negative. Options for oral drugs include moxifloxacin or levofloxacin, bedaquiline, linezolid, clofazimine, and cycloserine under expert guidance.[A11,A12] Pyrazinamide and ethambutol are oral options if other, more effective drugs cannot be used to construct a five-drug regimen. If an effective all-oral regimen cannot be constructed, amikacin or a carbapenem (imipenem or meropenem) in conjunction with amoxicillin-clavulanate (as a source of clavulanate) may be used under expert guidance if the isolate is sensitive to these agents. Partial surgical resection in conjunction with medical therapy can be considered in selected patients who have localized pulmonary multidrug-resistant TB.

Extensive drug resistance (XDR-TB) is a subset of multidrug-resistant TB, with resistance to at least isoniazid, rifampin, a fluoroquinolone, and a second-line injectable agent (amikacin or streptomycin). Pre-extensively drug-resistant TB is an intermediate step between multidrug-resistant TB and extensively drug-resistant TB, with retained susceptibility to either a fluoroquinolone or to second-line injectable agents. The standard treatment approach to extensively drug-resistant TB and pre-extensively drug-resistant TB parallels multidrug-resistant TB treatment principles, with a total treatment duration of between 15 and 24 months after culture conversion. As with multiple-drug-resistant TB, treatment of extensive drug-resistant TB requires the assistance of an expert. A shorter option is a seven-drug regimen (moxifloxacin, kanamycin, ethionamide, clofazimine, high-dose isoniazid, pyrazinamide, and ethambutol) for 4 to 6 months, followed by four drugs (moxifloxacin, clofazamine, pyrazinamide, and ethambutol) for another 5 to 6 months, for a total course of 9 to 12 months.[A13,A14] A promising 6-month regimen combining bedaquiline (400 mg orally daily for 2 weeks, then 200 mg 3 times weekly for 24 weeks, for a total duration of 26 weeks), pretomanid (200 mg orally daily for 26 weeks), and linezolid (1200 mg orally daily for 26 weeks, with dose reductions to 600 mg for adverse reactions and further reduction to 300 mg for myelosuppression, peripheral neuropathy, or optic neuropathy) has shown good outcomes in patients with multidrug-resistant and extensively drug-resistant TB.

PREVENTION

Preventing future TB cases requires disrupting the infection cycle by preventing new infections and the reactivation of latent TB infection. Testing of household contacts of patients with pulmonary TB is an important aspect of preventing TB and central to infection control programs. Active case finding, prompt diagnosis, and effective treatment all limit the duration that a person is infectious. Optimizing environmental factors to minimize crowding and enhance ventilation also prevent transmission. In clinical settings, patients should be placed in negative air pressure rooms with high-efficiency particulate air (HEPA) filtration. The infected patient should wear a surgical mask, and health care personnel should wear a fit-tested N95 mask to reduce transmission of infectious respiratory particles.[29]

The global burden of individuals with latent tuberculosis infection represents a constant source of new infections. Treating patients with latent tuberculosis infection reduces their risk of developing active TB by 75 to 90%. In low-prevalence settings, recommendations focus on identifying and treating individuals by targeting the testing for latent tuberculosis infection towards persons who are at high risk of recent infection or progression to active disease (see Diagnosis and Treatment sections, earlier). Treatment of latent tuberculosis infection requires resources that are often beyond what is available in resource-limited settings, so it is not a common practice in high-burden countries. With a quarter of the world potentially infected with TB, being able to target latent tuberculosis infection treatment to persons most at risk of reactivation would strongly help focus resources of global infection control programs. For example, among people living with HIV, early initiation of antiretroviral therapy can prevent the development of active TB. Considerable interest has also focused on identifying biomarkers that might predict which individuals are at highest risk of reactivation. Transcriptomic-based risk signatures can discriminate between individuals who are likely to progress to active TB over 6 to 12 months, but a recent clinical trial failed to show benefit of signature-guided preventive therapy in reducing progression to active disease.[A15] For persons living with HIV in highly endemic areas outside of the United States where reinfection is likely, secondary prevention therapy with daily isoniazid (300 mg daily) for 6 months or with rifapentine/isoniazid (900 mg/900 mg) given once weekly for 3 months each year may reduce the likelihood of active infection.[A16]

An effective vaccine that prevents infection or disease progression would have a major impact in the TB epidemic. The bacille Calmette-Guérin (BCG) vaccine (an attenuated strain of *Mycobacterium bovis*) is effective in preventing severe forms of TB in children, but it does not provide reliable protection against active pulmonary disease in adults. In nonhuman primates, a CMV-based vaccine and BCG administered by the intravenous route provided unprecedented levels of protection. Although neither of these approaches may be clinically feasible, they provide, for the first time, the opportunity to define correlates of protection. In addition, a recent clinical trial in adolescents who received a booster of the BCG vaccine showed a potential reduction in infection,[A17] and the M72/AS01$_E$ vaccine candidate reduced disease progression in patients with latent tuberculosis infection.[A18] These recent advances provide an optimistic outlook for the development of a preventative or therapeutic TB vaccine.

PROGNOSIS

In the absence of treatment, approximately 50% of patients who develop active TB disease will succumb to it. By comparison, patients who have drug-susceptible TB and who successfully complete therapy have cure rates approaching 100%. For multiple-drug-resistant and extensive drug-resistant TB, the cure rates are 50 to 60% and 2 to 22%, respectively, but outcomes have been improving with new drug combinations. For example, a recent clinical trial using bedaquiline, pretomanid, and linezolid had a success rate of 90% in patients with extensive drug-resistant TB.[A19] Overall, treatment success is now reported in 85% of patients globally and 95% of patients in the United States.

After the first 2 weeks of effective treatment of pulmonary TB, bacterial colony counts decline by 99.9%, cough decreases, and patients quickly become noninfectious. Patients who have HIV and TB coinfection with drug-susceptible TB convert their sputum culture from positive to negative as quickly as non–HIV-infected patients and have similar outcomes compared with non–HIV-infected patients. However, patients who are successfully treated for pulmonary TB often have permanently impaired lung function.

Favorable outcomes for people living with HIV, the elderly, patients with diabetes, and other patients who have compromised immune systems depend upon early diagnosis and appropriate treatment.

If untreated, TB meningitis is rapidly fatal, with a median time to death from symptom onset of 19 days. Patients with TB meningitis have a mortality rate of about 25%, and HIV patients with TB meningitis have a mortality rate of nearly 50%, even when treated.

300 THE NONTUBERCULOUS MYCOBACTERIA

STEVEN M. HOLLAND AND KENNETH N. OLIVIER

DEFINITION

Nontuberculous mycobacteria generally include the growing number of mycobacteria other than *Mycobacterium tuberculosis* and its close relatives (Chapter 299) and *M. leprae* (Chapter 301). Other names that have been used include *atypical mycobacteria*, *mycobacteria other than tuberculosis*, and *environmental mycobacteria*. Over 190 species of nontuberculous mycobacteria are now known, and the number continues to grow as DNA sequencing identifies additional species.

The Pathogens

Nontuberculous mycobacteria are acid-fast bacteria that differ from tuberculous mycobacteria, primarily by their reservoir or mode of acquisition. Nontuberculous mycobacteria are acquired from the environment, whereas *M. tuberculosis* is acquired primarily from person-to-person transmission. Nontuberculous mycobacteria are broadly differentiated into rapidly growing (<7 days) and slowly growing (>7 days) forms. *M. tuberculosis*, by contrast, typically requires 2 or more weeks to grow. Formation of pigment in light (photochromogens) or dark (scotochromogens) and lack of pigment (nonchromogens) can also help categorize nontuberculous mycobacteria. Current diagnostics use both mass spectrometry and molecular based methods including probes or gene sequencing for speciation (Table 300-1). For purposes of diagnosis, prognosis, and therapy, identification of nontuberculous mycobacteria should be taken to the species level.

EPIDEMIOLOGY

As a group, the nontuberculous mycobacteria are ubiquitous in soil and water. They are often found in certain animals (e.g., *M. avium* subspecies *paratuberculosis* cause Johne disease in cattle, whereas *M. avium* or *M. genavense* cause avian tuberculosis), but they rarely cause disease in humans. Human-to-human transmission of nontuberculous mycobacteria is rare, but *M. abscessus* subspecies *massiliense* has caused outbreaks of infection in cystic fibrosis centers.

Because these infections are not reported to health agencies and because their identification is sometimes problematic, reliable data on incidence and prevalence are lacking. Worldwide, documented infections with nontuberculous mycobacteria are increasing,[1] and isolates of nontuberculous mycobacteria have exceeded those for *M. tuberculosis* in the United States for many years. In patients with cystic fibrosis (Chapter 77), for example, rates of clinical nontuberculous mycobacterial infection range up to 40% in older patients, but even more patients harbor the organism. Differentiating active disease from commensal harboring of the organism remains problematic. Other patients, including patients with bronchiectasis (Chapter 78), also have elevated but undefined rates of nontuberculous mycobacterial infection. The bulk of nontuberculous mycobacterial disease in North America is due to *M. kansasii*, *M. avium* complex (MAC),[2] and *M. abscessus*.

Predisposing factors for lung infections include underlying lung disease,[3] such as bronchiectasis (Chapter 78),[4] pneumoconiosis (Chapter 81), chronic obstructive pulmonary disease (Chapter 76), primary ciliary dyskinesia (Chapter 78), and cystic fibrosis (Chapter 77).[5] Bronchiectasis and nontuberculous mycobacterial infection often coexist and progress in tandem, thereby making causality difficult to determine. Patients with pulmonary alveolar proteinosis (Chapter 79) are prone to pulmonary nontuberculous mycobacterial and *Nocardia* infections (Chapter 306), likely reflecting their association with anti–granulocyte-macrophage colony-stimulating factor (anti–GM-CSF) autoantibodies and impaired alveolar macrophage function.

M. avium complex infection most commonly occurs in women in their sixth or seventh decades. When compared with male smokers with upper lobe cavitary disease, who tend to carry the very same single strain of *M. avium* complex indefinitely, nonsmoking females with nodular bronchiectasis tend to have several strains simultaneously, which also change over the course of their disease process.

Esophageal motility disorders such as achalasia (Chapter 124) have been associated with pulmonary disease, especially that caused by rapidly growing nontuberculous mycobacteria such as *M. abscessus*. Numerous outbreaks of skin infections caused by rapidly growing mycobacteria have been due to skin contamination from instruments used for surgical procedures (especially cosmetic surgery), injections, and other procedures.

PATHOBIOLOGY

Exposure to nontuberculous mycobacteria is essentially universal, but disease is rare, so normal host defenses must be highly effective. For *M. avium* complex, the portal of entry that leads to dissemination is the bowel, with subsequent spread to bone marrow and the blood stream.

$CD4^+$ T lymphocytes are key effectors against nontuberculous mycobacteria, and patients with advanced human immunodeficiency virus (HIV) infection are especially susceptible to disseminated mycobacterial infection (Chapter 358).

300 THE NONTUBERCULOUS MYCOBACTERIA

STEVEN M. HOLLAND AND KENNETH N. OLIVIER

DEFINITION

Nontuberculous mycobacteria generally include the growing number of mycobacteria other than *Mycobacterium tuberculosis* and its close relatives (Chapter 299) and *M. leprae* (Chapter 301). Other names that have been used include *atypical mycobacteria*, *mycobacteria other than tuberculosis*, and *environmental mycobacteria*. Over 190 species of nontuberculous mycobacteria are now known, and the number continues to grow as DNA sequencing identifies additional species.

The Pathogens

Nontuberculous mycobacteria are acid-fast bacteria that differ from tuberculous mycobacteria, primarily by their reservoir or mode of acquisition. Nontuberculous mycobacteria are acquired from the environment, whereas *M. tuberculosis* is acquired primarily from person-to-person transmission. Nontuberculous mycobacteria are broadly differentiated into rapidly growing (<7 days) and slowly growing (>7 days) forms. *M. tuberculosis*, by contrast, typically requires 2 or more weeks to grow. Formation of pigment in light (photochromogens) or dark (scotochromogens) and lack of pigment (nonchromogens) can also help categorize nontuberculous mycobacteria. Current diagnostics use both mass spectrometry and molecular based methods including probes or gene sequencing for speciation (Table 300-1). For purposes of diagnosis, prognosis, and therapy, identification of nontuberculous mycobacteria should be taken to the species level.

EPIDEMIOLOGY

As a group, the nontuberculous mycobacteria are ubiquitous in soil and water. They are often found in certain animals (e.g., *M. avium* subspecies *paratuberculosis* cause Johne disease in cattle, whereas *M. avium* or *M. genavense* cause avian tuberculosis), but they rarely cause disease in humans. Human-to-human transmission of nontuberculous mycobacteria is rare, but *M. abscessus* subspecies *massiliense* has caused outbreaks of infection in cystic fibrosis centers.

Because these infections are not reported to health agencies and because their identification is sometimes problematic, reliable data on incidence and prevalence are lacking. Worldwide, documented infections with nontuberculous mycobacteria are increasing,[1] and isolates of nontuberculous mycobacteria have exceeded those for *M. tuberculosis* in the United States for many years. In patients with cystic fibrosis (Chapter 77), for example, rates of clinical nontuberculous mycobacterial infection range up to 40% in older patients, but even more patients harbor the organism. Differentiating active disease from commensal harboring of the organism remains problematic. Other patients, including patients with bronchiectasis (Chapter 78), also have elevated but undefined rates of nontuberculous mycobacterial infection. The bulk of nontuberculous mycobacterial disease in North America is due to *M. kansasii*, *M. avium* complex (MAC),[2] and *M. abscessus*.

Predisposing factors for lung infections include underlying lung disease,[3] such as bronchiectasis (Chapter 78),[4] pneumoconiosis (Chapter 81), chronic obstructive pulmonary disease (Chapter 76), primary ciliary dyskinesia (Chapter 78), and cystic fibrosis (Chapter 77).[5] Bronchiectasis and nontuberculous mycobacterial infection often coexist and progress in tandem, thereby making causality difficult to determine. Patients with pulmonary alveolar proteinosis (Chapter 79) are prone to pulmonary nontuberculous mycobacterial and *Nocardia* infections (Chapter 306), likely reflecting their association with anti–granulocyte-macrophage colony-stimulating factor (anti–GM-CSF) autoantibodies and impaired alveolar macrophage function.

M. avium complex infection most commonly occurs in women in their sixth or seventh decades. When compared with male smokers with upper lobe cavitary disease, who tend to carry the very same single strain of *M. avium* complex indefinitely, nonsmoking females with nodular bronchiectasis tend to have several strains simultaneously, which also change over the course of their disease process.

Esophageal motility disorders such as achalasia (Chapter 124) have been associated with pulmonary disease, especially that caused by rapidly growing nontuberculous mycobacteria such as *M. abscessus*. Numerous outbreaks of skin infections caused by rapidly growing mycobacteria have been due to skin contamination from instruments used for surgical procedures (especially cosmetic surgery), injections, and other procedures.

PATHOBIOLOGY

Exposure to nontuberculous mycobacteria is essentially universal, but disease is rare, so normal host defenses must be highly effective. For *M. avium* complex, the portal of entry that leads to dissemination is the bowel, with subsequent spread to bone marrow and the blood stream.

$CD4^+$ T lymphocytes are key effectors against nontuberculous mycobacteria, and patients with advanced human immunodeficiency virus (HIV) infection are especially susceptible to disseminated mycobacterial infection (Chapter 358).

ABSTRACT

Nontuberculous mycobacterial infections are increasing in frequency but remain difficult to diagnose and complicated to manage. The two broad categories of clinical disease are disseminated disease and pulmonary disease. Disseminated disease, which often occurs earlier in life, reflects immune failure to restrict nontuberculous mycobacteria to epithelial compartments and is almost always due to an underlying immune deficiency, either congenital (e.g., mutations in the IFN-γ/IL-12 pathway) or acquired (e.g., HIV). Autoantibodies to IFN-γ block the critical cytokine pathway that controls nontuberculous mycobacteria, thereby leading to disseminated disease. In contrast, pulmonary disease tends to occur in older adults and almost never disseminates. Pulmonary disease usually occurs in the setting of bronchiectasis and may be associated with either underlying congenital lung disease (e.g., cystic fibrosis or primary ciliary dyskinesia) or acquired lung disease (e.g., tobacco-related damage). Although these infections are typically acquired from the environment, person-to-person transmission can occur among patients who have cystic fibrosis. *Mycobacterium abscessus* lung disease is increasing in North America. Prolonged multidrug therapy, which is the cornerstone of treatment, may extend over years, especially for lung disease.

KEYWORDS

interferon gamma
interleukin-12
bronchiectasis
immunodeficiency
disseminated

Specific mutations in the interferon (IFN)-γ/interleukin (IL)-12 synthesis and response pathways also predispose to dissemination, but only about 70% of non-HIV patients with disseminated infection have an identifiable genetic mutation. Autoantibodies to IFN-γ mimic genetic defects in the pathway.

Mycobacteria are typically phagocytosed by macrophages, which respond with the production of IL-12, a heterodimer composed of p35 and p40 moieties that together constitute IL-12p70 (E-Fig. 300-1). IL-12 activates T lymphocytes and natural killer (NK) cells through binding to its receptor (composed of IL-12Rβ1 and IL-12Rβ2/IL-23R) and results in phosphorylation of STAT4 (signal transducer and activator of transcription 4). IL-12 stimulation leads to production and secretion of IFN-γ, which activates neutrophils and macrophages to produce reactive oxidants and increase major histocompatibility complex display and Fc receptors. IFN-γ signals through its receptor (composed of IFN-γR1 and IFN-γR2), thereby leading to phosphorylation of STAT1, which in turn regulates IFN-γ–responsive genes such as those for the production of IL-12 and tumor necrosis factor (TNF)-α. Therefore, the positive feedback loop between IFN-γ and IL-12/IL-23 is pivotal in the immune response to mycobacteria and other intracellular infections (most importantly *Salmonella* [Chapter 284], *Histoplasma* [Chapter 308], and *Coccidioides* [Chapter 308]). The advent of potent TNF-α inhibitors such as infliximab, adalimumab, certolizumab, etanercept, and golimumab (Chapter 29) has provided the ability to neutralize this critical cytokine to treat inflammatory disease but at the expense of an increased risk for developing mycobacterial and fungal infections.

Nontuberculous mycobacterial osteomyelitis is especially common in patients who have dominant negative mutations in IFN-γR1. Adult-onset disseminated disease may be associated with GATA2 deficiency (monocytopenia, NK and B cell cytopenia). Some patients with disseminated disease, especially women from southeast Asia, have high-titer autoantibodies to IFN-γ.

CLINICAL MANIFESTATIONS

Disseminated Disease

Disseminated nontuberculous mycobacterial disease secondary to *M. avium* complex can occur commonly in the setting of advanced HIV and the acquired immunodeficiency syndrome (AIDS). This infection is now uncommon in North America because of prophylaxis and improved treatment of HIV infection[6] with highly active antiretroviral therapy (Chapter 357), but it remains a problem in many parts of the developing world.

Rapidly growing mycobacteria such as *M. fortuitum* sometimes infect central venous catheters. The severe disseminated infection seen with immune defects is typically associated with malaise, fever, and weight loss. It is often accompanied by organomegaly and lymphadenopathy.

Pulmonary Disease

Lung disease caused by nontuberculous mycobacteria is by far the most common form of the infection in North America. *M. avium* complex infection is typically associated with months to years of frequent throat clearing, a chronic cough that may be nonproductive early in the clinical course, and fatigue. The manifestations of *M. kansasii* infection, which can be very similar to those of tuberculosis (Chapter 299), consist of hemoptysis, chest pain, and cavitary lung disease.

Lung disease rarely disseminates, thereby illustrating that the defects leading to isolated pulmonary involvement are specific to the respiratory epithelium, whereas those defects leading to disseminated disease affect immune cells. Therefore, evaluation of isolated lung disease should focus on respiratory tract causes.

Cervical Lymph Nodes

Isolated cervical lymphadenopathy, most frequently caused by *M. avium* complex, is the most common form of nontuberculous mycobacterial infection in young children in North America. However, other nontuberculous mycobacteria such as *M. canettii*, which is mostly seen in Africa, also cause adenitis.[7] The cervical swelling is often firm and relatively painless with a paucity of systemic signs. Because the differential diagnosis of painless adenopathy (Chapter 154) includes malignancy, many of these infections are incidentally diagnosed at biopsy. Local fistulae usually resolve completely with resection or antibiotic therapy or both.

Skin and Soft Tissue Disease

M. marinum causes skin infections, usually papules or ulcers, associated with water exposure and is known as "fish tank granuloma."[8,9] Skin infections associated with *M. abscessus*, *M. fortuitum*, and *M. chelonae* are typically accompanied by painful, erythematous, draining subcutaneous nodules, usually without associated fever or systemic symptoms. *M. ulcerans* infection, which mostly occurs in West Africa, Australia, and Central America, causes Buruli ulcer disease, in which painless swelling progresses to large ulcers, usually on the arms and legs.

DIAGNOSIS

Identifying the Organism

Nontuberculous mycobacteria are now the most common mycobacteria isolated from humans in North America.[10] *M. kansasii*, *M. szulgai*, and *M. marinum* all can cross react in the standard interferon gamma release assay (IGRA) for *M. tuberculosis*. Isolation of nontuberculous mycobacteria from blood specimens is clear evidence of disease.

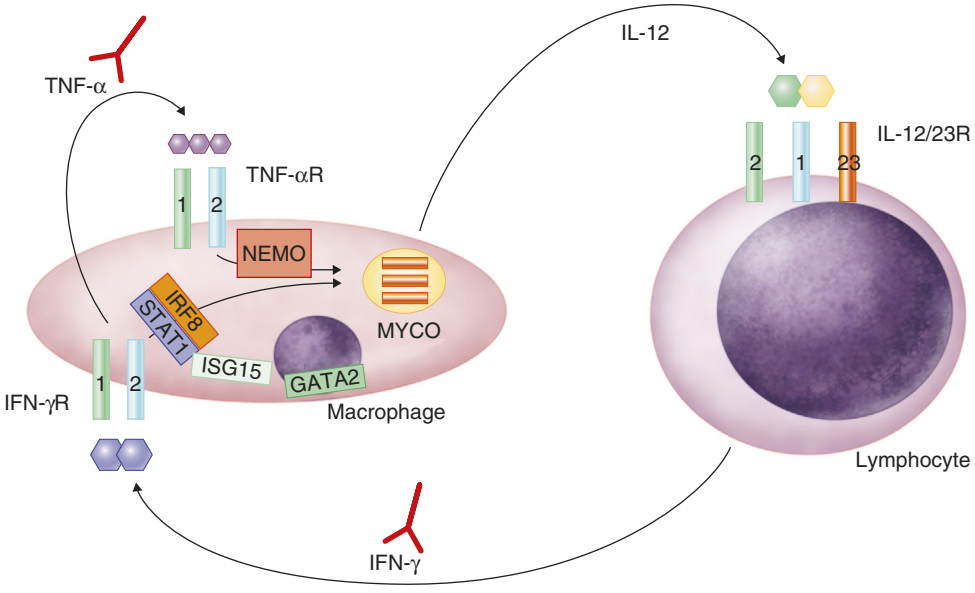
Usually, however, nontuberculous mycobacteria are typically first detected on acid-fast smears of sputum or other body fluids. When levels of organisms are high, mycobacteria may be seen on Gram stain as gram-positive beaded rods, but this finding is unreliable. The first step in identification is to request the appropriate smear (acid-fast or fluorochrome) and culture. Direct nucleic acid amplification tests such as real-time polymerase chain reaction (PCR) and digital PCR can decrease the detection time and may increase sensitivity. However, they cannot distinguish between living and dead organisms or between causative pathogen and contaminants in respiratory specimens. The application of PCR and matrix-assisted laser desorption-ionization time-of-flight assays on liquid cultures grown in mycobacteria growth indicator tubes have the potential to accelerate the identification of the specific mycobacterial species.[11]

Because the slow-growing nontuberculous mycobacteria typically do not grow well in routine blood culture media, the diagnosis must be suspected to be made. Isolation of nontuberculous mycobacteria from a biopsy specimen is strong evidence of infection, but cases of laboratory contamination can occur. Identification of organisms on stained sections of biopsy material confirms the authenticity of the culture. Some unusual nontuberculous mycobacteria require lower incubation temperatures or special additives for growth (e.g., *M. haemophilum*).

Radiology

The radiographic appearance of nontuberculous mycobacterial disease in the lung is similar to that seen in tuberculosis and ranges from nodules and bronchiectasis to air space disease and extensive cavity formation (Fig. 300-1).[12] The presence of bronchiectatic changes or especially cavitation on a chest computed tomographic (CT) scan can help distinguish active infection from colonization.[13]

FIGURE 300-1. **Chest computed tomography in a patient with severe pulmonary *Mycobacterium abscessus* infection.** *Arrows* indicate bronchiectasis. Note the extensive left upper lobe destruction and diffuse pleural reaction. In addition, the left lung is smaller than the right as a result of extensive loss of lung parenchyma.



E-FIGURE 300-1. Schematization of the critical cytokine interactions between infected macrophages and T and natural killer lymphocytes. Organisms (MYCO) infect macrophages, which release heterodimeric interleukin (IL)-12. This acts on the IL-12/23 receptor complex and leads to the production of homodimeric interferon (IFN)-γ. IFN-γ acts on its receptor to stimulate the production of tumor necrosis factor (TNF)-α and kill intracellular organisms such as mycobacteria, salmonellae, and some fungi. Homotrimeric TNF-α acts on its own receptor and also contributes to killing of intracellular organisms. Both IFN-γ and TNF-α lead to upregulation of IL-12. TNF-α–inhibitors work either by blocking the ligand (infliximab, adalimumab, certolizumab) or by providing soluble receptor (etanercept). Mutations in both chains of IFN-γR, IL-12p40, and IL-12Rβ1, IL-12Rβ2, and signal elements for IFN-γR and TNF-αR have been identified through their predisposition to mycobacterial infections. IRF8 = interferon regulatory factor 8; ISG = interferon-stimulated gene; NEMO = nuclear factor kappa-B essential modulator; STAT1 = signal transducer and activator of transcription 1.

Isolation of nontuberculous mycobacteria from respiratory samples presents special problems in both sensitivity and specificity. *M. gordonae* is often recovered from respiratory samples and is almost never thought to be a real pathogen. Many patients, especially patients with bronchiectasis, will occasionally have nontuberculous mycobacteria recovered from sputum culture without such mycobacteria being seen on smear.

Diagnostic Criteria

Criteria for definitive diagnosis of nontuberculous mycobacterial lung disease with *M. avium* complex, *M. abscessus*, and *M. kansasii* require characteristic symptoms and radiographic findings plus: two of three sputum samples grow nontuberculous mycobacteria, regardless of smear findings; a positive bronchoscopic alveolar sample, regardless of smear findings; or a biopsy specimen of pulmonary parenchyma showing either granulomatous inflammation or mycobacteria and growing nontuberculous mycobacteria on culture. These guidelines are likely useful for other nontuberculous mycobacteria as well.

Additional Evaluation

Disseminated (two or more organs) involvement in a child without an underlying iatrogenic cause should always prompt an investigation of the IFN-γ/IL-12 pathway. Since the advent of effective antiretroviral therapy, disseminated mycobacterial infection has become much less common in HIV-infected persons. However, HIV infection should always be considered when a patient has disseminated mycobacterial infection and a low CD4 count (Chapter 358).

TREATMENT

General Principles

Emergency treatment is rarely indicated for nontuberculous mycobacterial infections, which are relatively slowly progressive, chronic infections that evolve over a period of weeks to years, not hours to days. Some asymptomatic or minimally symptomatic patients who have respiratory infection but have negative smears, are not underweight, and do not have lung cavities are at lower risk for progression and may require no therapy. In these cases, the decision to treat can be deferred unless and until the patient progresses on clinical follow-up as evidenced by increased symptoms, radiographic changes, or an increased burden of organisms.[14,15] In asymptomatic patients in whom a pulmonary nodule incidentally shows nontuberculous mycobacteria, surgical resection also can be adequate therapy.[16,17] Therefore, empiric medical therapy usually is not needed, and identification of the species is advisable before starting complex, often poorly tolerated, and potentially toxic regimens.

Once isolated, the nontuberculous mycobacteria should be classified to help determine the broad class of antimycobacterial therapy to be used.[18] Initial isolates of *M. avium* complex that have not been exposed to macrolides are almost always susceptible to them. Drug susceptibility testing is of limited and largely unproven value. For pulmonary disease, however, clarithromycin and amikacin susceptibility testing is recommended for *M. avium* complex and *M. abscessus* and rifampin susceptibility testing is recommended for *M. kansasii*. Any nontuberculous mycobacteria that have resisted a course of antimicrobials should probably be tested for antibiotic susceptibility as well. Similar to infection with tuberculosis, single-drug therapy is almost always associated with the emergence of antimicrobial resistance and is strongly discouraged.

Antibiotic and Surgical Treatment

M. avium complex infection frequently requires complex multidrug therapy, the foundation of which is a macrolide (clarithromycin or azithromycin), ethambutol, and a rifamycin (rifampin or rifabutin; see Table 300-2).[19] Treatment is recommended for 12 months after the sputum culture changes from positive to consistently negative. In patients who have cystic fibrosis and who are on CFTR modulator therapy (Chapter 77),[20] the use of rifamycins is contraindicated. For pulmonary *M. avium* complex disease with nodular bronchiectatic disease, three-times-weekly administration is adequate, but daily treatment with the addition of either streptomycin or amikacin is recommended for severe bronchiectatic or cavitary disease. Other drugs with activity against *M. avium* complex under the guidance of an expert include amikacin (either intravenous or inhaled), fluoroquinolones, and clofazimine (see Table 300-2). Amikacin liposome inhalation suspension is useful for treatment-refractory pulmonary *M. avium* complex infections.[A1] Adjuvant pulmonary resection can be thoracoscopically performed in selected patients who have antibiotic-refractory disease with a relatively low complication rate and a relatively high level of success.[21]

M. kansasii lung disease is similar to tuberculosis in many ways, including its susceptibility to rifampin, and it is usually effectively treated with a three-drug combination of either isoniazid or a macrolide plus rifampin and ethambutol.[22] Treatment should continue for a fixed duration of 1 year. In patients with rifampin-resistant isolates, a fluoroquinolone is indicated, and amikacin may be needed for patients who do not respond. For skin ulcers caused by *M. ulcerans*, which is sensitive to temperatures above 37° C, local thermotherapy is highly effective and safe.

Rapidly growing mycobacteria such as *M. chelonae or M. abscessus* pose special therapeutic problems. Extrapulmonary disease in an immunocompetent host is usually due to inoculation (e.g., surgery, injection, trauma) or line

TABLE 300-2 DRUG DOSING FOR MANAGEMENT OF NONTUBERCULOUS MYCOBACTERIAL DISEASE

DRUG	DAILY	THRICE WEEKLY	HEPATIC ADJUSTMENT	RENAL ADJUSTMENT
Oral				
Azithromycin	250–500 mg per day	500 mg per day	N/A	N/A
Ciprofloxacin	500–750 mg twice per day	N/A	N/A	250–500 mg dosed at intervals according to CrCl
Clarithromycin	500 mg twice per day	500 mg twice per day	N/A	Reduce dose by 50% if CrCl <30 mL/min
Clofazimine	100–200 mg per day	N/A	Caution in severe hepatic impairment	N/A
Doxycycline	100 mg once to twice a day	N/A	N/A	N/A
Ethambutol	15 mg/kg per day	25 mg/kg per day	N/A	Increase dosing interval (e.g., 15–25 mg/kg , three times per week)
Isoniazid	5 mg/kg up to 300 mg per day	N/A	Caution	N/A
Linezolid	600 mg once or twice per day	N/A	N/A	N/A
Moxifloxacin	400 mg per day	N/A	N/A	N/A
Rifabutin	150–300 mg per day (150 mg per day with clarithromycin)	300 mg per day	Caution	Reduce dose by 50% if CrCl <30 mL/min
Rifampin	10 mg/kg (450 mg or 600 mg) per day	600 mg per day	Caution	N/A
Parenteral				
Amikacin (IV)	10–15 mg/kg per day, adjusted according to drug level monitoring	15–25 mg/kg per day, adjusted according to drug level monitoring	N/A	Reduce dose or increase dosing interval (e.g., 15 mg/kg, two to three times per week)
Cefoxitin (IV)	2–4 g, two to three times daily (maximum daily dose is 12 g per day)	N/A	N/A	Reduce dose or increase dosing interval
Imipenem (IV)	500–1000 mg, two to three times per day	N/A	N/A	Reduce dose or increase dosing interval

TABLE 300-2 DRUG DOSING FOR MANAGEMENT OF NONTUBERCULOUS MYCOBACTERIAL DISEASE—cont'd

DRUG	DAILY	THRICE WEEKLY	HEPATIC ADJUSTMENT	RENAL ADJUSTMENT
Streptomycin (IV or IM)	10–15 mg/kg per day, adjusted according to drug level monitoring	15–25 mg/kg per day, adjusted according to drug level monitoring	N/A	Reduce dose or increase dosing interval (e.g., 15 mg/kg, two to three times per week)
Tigecycline (IV)	25–50 mg once or twice per day	N/A	25 mg once or twice daily per day if severe hepatic impairment	N/A
Inhalation				
Amikacin liposome inhalation suspension	590 mg per day	N/A	N/A	N/A
Amikacin, parenteral formulation	250–500 mg per day	N/A	N/A	N/A

Adapted from Daley CL, Iaccarino JM, Lange C, et al. Treatment of nontuberculous mycobacterial pulmonary disease: an official ATS/ERS/ESCMID/IDSA clinical practice guideline. *Eur Respir J.* 2020;56:2000535.

infection and is often treated successfully with a macrolide, either clarithromycin or azithromycin, plus another drug, which may be guided by in vitro susceptibility, along with removal of the offending focus. By comparison, pulmonary disease, especially infection caused by *M. abscessus*, is extremely difficult to eradicate if it is macrolide resistant, although repeated courses of treatment are usually effective in reducing the infectious burden and symptoms. Therapy generally includes a macrolide, either clarithromycin or azithromycin (if susceptible), plus intravenous agents such as amikacin, a carbapenem, cefoxitin, or tigecycline. Other oral agents, guided by in vitro susceptibility testing and tolerance, include fluoroquinolones, omadacycline, clofazimine, and linezolid along with inhaled amikacin.

In patients with *Mycobacterium ulcerans*, once daily oral rifampicin (10 mg/kg) plus oral clarithromycin (15 mg/kg extended release) for 8 weeks is as effective as oral rifampicin (10 mg/kg) plus intramuscular streptomycin (15 mg/kg once daily) for 8 weeks for the treatment of early Buruli ulcer lesions, with cure rates of about 95%.[A2] Treatment of the other nontuberculous mycobacteria is less well defined, but macrolides and aminoglycosides are usually effective, with other agents added as indicated under expert consultation.[23]

Treatment in HIV-Infected Patients

The treatment of *M. avium* complex in HIV-infected patients is described in Chapter 358 (see Table 358-2).

PREVENTION

Prophylaxis of *M. avium* complex disease in patients infected with HIV is started when the $CD4^+$ T-lymphocyte count is less than 50 cells/μL. Azithromycin 1200 mg weekly, clarithromycin 1000 mg daily, and rifabutin 300 mg daily are effective.

PROGNOSIS

The effect of nontuberculous mycobacterial infection on longevity is closely tied to the underlying condition (e.g., IFN-γ/IL-12 pathway defect, HIV, cystic fibrosis). With inadequate treatment, symptoms can be intrusive, and the infections can lead to fatal complications, including overwhelming infection or severe lung destruction. When treatment is indicated, the failure to follow guideline-based treatment is associated with poorer outcomes.[24]

301 LEPROSY (HANSEN DISEASE)

SUNIL DOGRA

DEFINITION

Leprosy (Hansen disease), which is caused by *Mycobacterium leprae,* is a chronic infection found worldwide but with about 75% of cases reported in India, Brazil, and Indonesia.[1] The primary clinical manifestation is hypopigmented, hypoesthetic or anesthetic, nonpruritic skin lesions. Peripheral nerve damage, which can be a result of the immune response to the infection, leads to loss of sensation and decreased motor function. The peripheral neuropathy (Chapter 388) can be complicated by painless injuries, secondary bacterial infections, and muscle atrophy and contractures. Leprosy is not a fatal disease, but the debility associated with leprosy increases the risk of death from malnutrition or other infections. Although the transmissibility of *M. leprae* is low and effective medications can cure it, the substantial stigma associated with it remains an ongoing challenge.

The Pathogen

M. leprae is a nonmotile, non–spore forming, microaerophilic, acid-fast staining, slow-growing, rod-shaped bacterium measuring 1 to 8 microns in length and 0.3 microns in diameter. *M. leprae* contains a mycolic acid-rich cell wall and a single membrane. *M. leprae,* which has an average generation time of 14 days, probably evolved from the same common ancestor as *M. tuberculosis,* but it has approximately 2000 fewer genes and lacks the genes that are necessary for independent growth. *M. leprae* needs an optimum temperature of about 30° C, so it mostly involves cooler parts of the body, such as the ears, nose, and the superficial course of peripheral nerves. *M. leprae* cannot be cultivated in vitro in any artificial medium, but propagation of *M. leprae* in mouse foot pads provides a tool for assessing the viability of a preparation of bacteria and testing the drug susceptibility of clinical isolates.

EPIDEMIOLOGY

Leprosy is a neglected tropical disease that has reached a crucial junction of worldwide control. The targeted goal of fewer than 10 cases per 10,000 population was achieved globally in 2000 and in India in 2005. However, leprosy still occurs in more than 120 countries, with more than 200,000 annual new cases, about 75% of which are from India, Indonesia and Brazil.[2] During the severe acute respiratory syndrome coronavirus-2019 (SARS-CoV-19) pandemic, the case detection rate declined, and only about 130,000 cases were on treatment worldwide in 2020 for a rate of 16.6 per million population. During 2021, 140,594 new cases were reported globally for a case detection rate of about 18 per million population. The rate of detection of new cases increased by 10.2% as compared with 2020. In the U.S., leprosy is extremely uncommon, with fewer than 250 cases diagnosed annually, mostly in immigrants from India, Brazil, the Philippines, the Dominican Republic, and Mexico.

301 LEPROSY (HANSEN DISEASE)

SUNIL DOGRA

DEFINITION

Leprosy (Hansen disease), which is caused by *Mycobacterium leprae,* is a chronic infection found worldwide but with about 75% of cases reported in India, Brazil, and Indonesia.[1] The primary clinical manifestation is hypopigmented, hypoesthetic or anesthetic, nonpruritic skin lesions. Peripheral nerve damage, which can be a result of the immune response to the infection, leads to loss of sensation and decreased motor function. The peripheral neuropathy (Chapter 388) can be complicated by painless injuries, secondary bacterial infections, and muscle atrophy and contractures. Leprosy is not a fatal disease, but the debility associated with leprosy increases the risk of death from malnutrition or other infections. Although the transmissibility of *M. leprae* is low and effective medications can cure it, the substantial stigma associated with it remains an ongoing challenge.

The Pathogen

M. leprae is a nonmotile, non–spore forming, microaerophilic, acid-fast staining, slow-growing, rod-shaped bacterium measuring 1 to 8 microns in length and 0.3 microns in diameter. *M. leprae* contains a mycolic acid-rich cell wall and a single membrane. *M. leprae,* which has an average generation time of 14 days, probably evolved from the same common ancestor as *M. tuberculosis,* but it has approximately 2000 fewer genes and lacks the genes that are necessary for independent growth. *M. leprae* needs an optimum temperature of about 30° C, so it mostly involves cooler parts of the body, such as the ears, nose, and the superficial course of peripheral nerves. *M. leprae* cannot be cultivated in vitro in any artificial medium, but propagation of *M. leprae* in mouse foot pads provides a tool for assessing the viability of a preparation of bacteria and testing the drug susceptibility of clinical isolates.

EPIDEMIOLOGY

Leprosy is a neglected tropical disease that has reached a crucial junction of worldwide control. The targeted goal of fewer than 10 cases per 10,000 population was achieved globally in 2000 and in India in 2005. However, leprosy still occurs in more than 120 countries, with more than 200,000 annual new cases, about 75% of which are from India, Indonesia and Brazil.[2] During the severe acute respiratory syndrome coronavirus-2019 (SARS-CoV-19) pandemic, the case detection rate declined, and only about 130,000 cases were on treatment worldwide in 2020 for a rate of 16.6 per million population. During 2021, 140,594 new cases were reported globally for a case detection rate of about 18 per million population. The rate of detection of new cases increased by 10.2% as compared with 2020. In the U.S., leprosy is extremely uncommon, with fewer than 250 cases diagnosed annually, mostly in immigrants from India, Brazil, the Philippines, the Dominican Republic, and Mexico.

ABSTRACT

Leprosy (also known as Hansen disease) is a neglected tropical disease that results from infection with *Mycobacterium leprae*. The target level of leprosy elimination (<10 cases/10,000 population) was achieved at the global level by the year 2000 and at the national level in India in 2005. However, leprosy still occurs in more than 120 countries worldwide, and more than 200,000 new cases were noted annually (about 75% of which were reported from India, Indonesia, and Brazil) before the severe acute coronavirus syndrome-2019 (SARS-CoV-19) pandemic resulted in lower reported rates. In 2020, about 130,000 patients were being actively treated for leprosy. During 2021, 140,594 new cases were reported globally. The most common clinical manifestations are skin lesions and peripheral neuropathy. Multidrug therapy can cure leprosy but does not reverse established nerve damage.

KEYWORDS

Hansen disease
leprosy

M. leprae can survive outside the human body in humid tropical environments for 7 to 10 days and in moist soil for a few weeks. Humans are thought to be the natural host for *M. leprae*, but it also grows in nine-banded armadillos found in the Americas. Other potential sources proposed for *M. leprae* are red squirrels,[3] non-human primates (mangabey monkeys), rats, and vectors such as amoeba, ticks, mosquitoes, soil, and water. However, there is little established evidence for other potential sources of *M. leprae* infection other than from humans.

Individuals with multibacillary disease are the major source of human spread, although transmission also can occur from paucibacillary cases. The usual route of transmission is respiratory droplets, but the organisms also may enter via breached skin. *M. leprae* is not highly transmissible. Even in endemic areas, leprosy is rare except in persons who have prolonged, close contact with infected cases,[4,5] so travelers are not at substantial risk.

PATHOBIOLOGY

Because only 0.1 to 1% of the exposed population develops clinical disease and the disease spectrum varies among infected individuals, the susceptibility to infection, progression to clinical disease, and the severity of disease are mostly determined by host factors.

Immunogenetics

By genome-wide scans, susceptibility to tuberculoid leprosy has been located to chromosomal region 10p13. Susceptibility genes associated with leprosy include major histocompatibility complex (MHC) loci (HLA-A*1102-B*4006-Cw*1502 haplotype and the human leukocyte antigen [HLA]-DRB1 locus). HLA-DR2 and HLA-DR3 genes, which are class II HLA/MHC genes, have been implicated in influencing the spectrum of disease a patient develops.[6] Single nucleotide polymorphisms also have been identified in tumor necrosis factor (TNF) alpha and interleukin (IL)-10 genes. Several genes are involved in the host's response to the *M. leprae*; some may have a role in the adaptive immune response (e.g., *HLA, TAP2 , VDR , PTPN22*), whereas others may have a role in innate immunity (e.g., *NRAMP1, TLR2 , MICA , TNF-α , MRC1*).[7] Depending on the alleles that an individual possesses, the individual may get a milder or more severe form of the disease or may be able to resist the infection entirely.

Pathogenesis

Dendritic antigen-presenting cells of the host recognize the lepra bacilli via their complement receptor and upregulate both MHC class II and CD40 ligands, thereby resulting in the production of IL-12. Subsequently, cytokines and chemokines, which are produced locally, regulate the type of infiltrate and thereby the course of cell-mediated immunity via a helper T-lymphocyte dominant response.[8] The pathophysiology is not exactly known, but the features resemble type III hypersensitivity as demonstrated by the deposition of antigen, antibody, and complement (immune complexes) in the dermis. The helper T-lymphocyte response drives immunity to *M. leprae* and determines whether an individual will develop tuberculoid or lepromatous leprosy. Patients with tuberculoid leprosy have a T-helper 1 (T_H1) response that is associated with production of IL-12, TNF-α, and IFN-γ, thereby favoring a delayed-type hypersensitivity reaction. Lepromatous disease is associated with a weak T_H1-type response and a relative increase in T_H2-type cytokines. T_H1 cytokines are associated with activation of toll-like receptor-1 (TLR1) and toll-like receptor-2 (TLR2), and whereas T_H2-type cytokines are associated with inhibition. The expression of TLR1 and TLR2 is stronger on monocytes and dendritic cells in tuberculoid leprosy than in the lepromatous lesions. As a result, lesions of tuberculoid leprosy have more lymphocytes and transformed macrophages, called epithelioid cells, because of cell-mediated immunity and the paucity of bacilli. By comparison, the lymphopenic lesions in lepromatous leprosy have numerous bacilli within macrophages. During the course of chronic disease, erythema nodosum leprosum occurs mainly in patients who have lepromatous/borderline leprosy. Classic histopathologic features of active erythema nodosum leprosum lesions are increased vascularity with dilated capillaries in the upper and lower dermis, as well as intense infiltration with neutrophils and generally fragmented and granular bacilli. Reversal reaction or type 1 reactions are associated with borderline leprosy (E-Fig. 301-1).

Pathogenesis of Nerve Damage

M. leprae has the unique ability to invade peripheral nerves, and its presence within a nerve fiber is a pathognomonic sign of leprosy. Leprosy neuropathy is a slowly progressive sensorimotor infective polyneuropathy. Invasion of Schwann cells and axons by *M. leprae* leads to demyelination and axonal degeneration. *M. leprae* binds to the G domain of the laminin alpha-2 chain that is expressed on the surface of the Schwann cell–axon unit, through a 21-kDa histone-like protein. The terminal trisaccharide of phenolic glycolipid 1, which is a surface-exposed *M. leprae*–specific antigen, helps to bind to laminin-2. Subsequently, *M. leprae* alter the interior milieu of the cell, thereby producing metabolic and functional changes in nerves. *M. leprae* prefer to localize in the cooler regions, so segments of nerve trunks that are superficial and in close contact with the skin are predominantly involved. Polyneuritis is severe during acute episodes of leprosy reactions and more so during type 1 reactions. The volume of the granuloma, its inflammatory cells, and intraneural and perineural edema cause pressure effects and axonal damage. Although polyneuritis continues to occur during the course of leprosy, these effects are accentuated during acute leprosy reactions. If untreated, this process progresses to nerve destruction, fibrosis, and irreversible nerve damage.

The neuropathic pain of leprosy can be caused by disorders of the somatosensory nervous system, owing to infection itself, or by lepromatous reactions to the infection. Neuropathic pain, which usually is observed in patients who have completed multidrug therapy, can persist for months to years. The pain is generally considered to be a small fiber sensory neuropathy, with painful paresthesia as its most common effect.

CLINICAL MANIFESTATIONS

The incubation period for leprosy is estimated to range from 2 to 20 years, with an average of 5 years, and about 95% of infected people may never develop clinical disease owing to their innate immune response. In the remaining individuals, the disease may self-resolve or it may progress to a clinical stage, which will resolve only if treated.

Leprosy commonly involves the skin and peripheral nerves, and its manifestations are determined by the polarity of the disease: paucibacillary (tuberculoid) or multibacillary (lepromatous). Patients commonly present with skin lesions,[9] weakness or numbness of hands or feet caused by a peripheral-nerve involvement, deformities, resorption of fingers and toes, or a burn or ulcer in an anesthetic hand or foot. Some patients may present with acute nerve pain, sudden palsy, new skin lesions, a painful red eye, or a systemic febrile illness.

Leprosy-related neuropathic pain includes a wide spectrum of symptoms, including paresthesia, dysesthesia, hyperesthesia (increased sensitivity to normal painful stimuli), and allodynia (pain in response to a stimulus that is not normally painful) along the nerve and in its area of distribution.[10] The reported prevalence of neuropathic pain in leprosy ranges from 11 to 70% in various studies. The neuropathic pain can be severely debilitating, affect a patient's quality of life, and result in substantial psychological distress.

Classification of Disease

Leprosy also can be categorized as paucibacillary or multibacillary, based on the number of skin lesions, nerve involvement, and bacteriologic status (Table 301-1). Another categorization based on clinical, bacteriologic, histologic, and immunologic features (Table 301-2) classifies leprosy as tuberculoid, borderline tuberculoid, borderline borderline, borderline lepromatous, and lepromatous leprosy.[11] In general, paucibacillary disease is equivalent to tuberculoid and borderline tuberculoid disease, whereas multibacillary is equated with borderline, borderline lepromatous, and lepromatous disease.

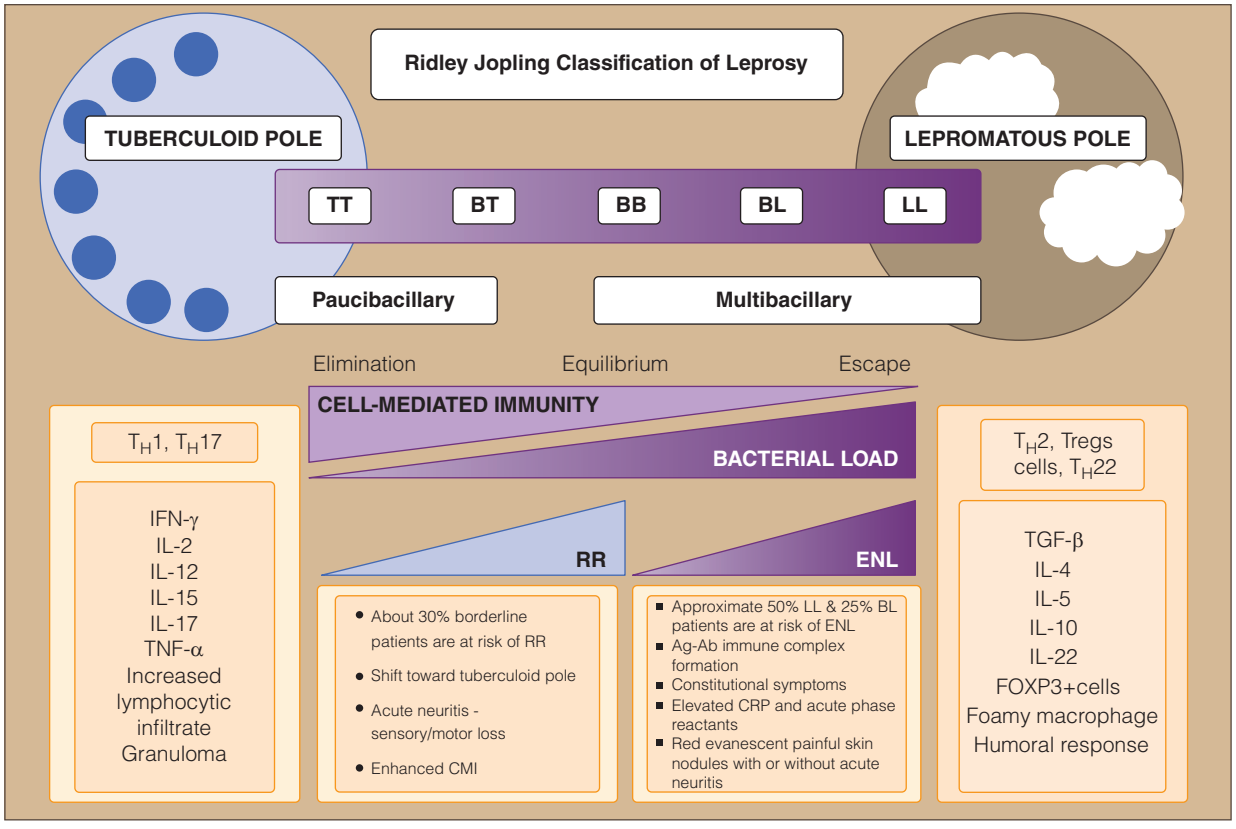
Tuberculoid Leprosy

Tuberculoid leprosy is a less common, benign, and relatively stable form of disease. The number of skin lesions is usually one to three, seldom measuring more than 10 cm in diameter and infrequently positive on bacteriologic examination. The typical lesion is a well-defined erythematous plaque with raised and clear-cut edges sloping inward. The surface is dry, hairless, anesthetic, and usually scaly. A solitary peripheral nerve trunk may be thickened

TABLE 301-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF LEPROSY

	CRITERIA
Paucibacillary	1 to 5 skin lesions, without bacilli in a skin smear and without nerve involvement
Multibacillary	Any one of: • More than five skin lesions • Nerve involvement (pure neuritic) • Any number of skin lesions and nerve involvement • Demonstrated presence of bacilli in a slit-skin smear, irrespective of the number of skin lesions

From World Health Organization. *Guidelines for the Diagnosis, Treatment and Prevention of Leprosy*. Geneva: World Health Organization; 2018.



E-FIGURE 301-1. The bacteriologic, immunologic, and clinical spectrum of leprosy. Towards the tuberculoid pole, cell-mediated immunity is strong, with predominance of a T-helper (T_H) and T_H17 immune response. This response keeps the bacillary load in check (paucibacillary), and biopsy specimens of skin lesions or slit skin smears reveal few or no bacilli. Lepromatous (multibacillary) leprosy has a strong T_H2 and regulatory T cell (Treg) response, which allows the bacilli to replicate; biopsy and slit skin smears are often teeming with acid-fast bacilli. The intermediate forms can resemble either tuberculoid or lepromatous leprosy, based on the host's prevalent immune response. BB = borderline borderline; BL = borderline lepromatous; BT = borderline tuberculoid; CMI = cell-mediated immunity; CRP = C-reactive protein; ENL = erythema nodosum leprosum; FOXP3 = forkhead box P3; IFN = interferon; IL = interleukin; LL = lepromatous; RR = reversal reaction; TGF = transforming growth factor; TT = tuberculoid leprosy.

TABLE 301-2 CHARACTERISTICS OF THE FIVE CLINICAL CLASSES OF LEPROSY *

OBSERVATION	TUBERCULOID LEPROSY	BORDERLINE TUBERCULOID	BORDERLINE BORDERLINE	BORDERLINE LEPROMATOUS	LEPROMATOUS LEPROSY
Number of lesions	Usually single (up to 3)	Few (up to 10)	Several (10-30)	Many (>30), asymmetrical	Innumerable, symmetrical
Size of lesions	Variable, usually large	Variable, some are large	Variable	Usually small, but some can be large	Small
Surface	Very dry, scaly, lesions look turgid	Dry, scaly, lesions look bright and infiltrated	Dull/slightly shiny	Shiny	Shiny
Sensations in lesions	Absent	Markedly diminished	Moderately diminished	Slightly diminished	Minimally diminished, not affected
Hair growth in lesions	Absent	Markedly diminished	Moderately diminished	Slightly diminished	Not affected initially, but almost all body hair is lost in long-standing disease
AFB in lesions	Nil	Nil or scanty	Moderate in number	Many	Plenty, including globi
Lepromin reactivity	Strongly positive (+++)	Weakly positive (+ or ++)	Negative/ weakly positive –/+	Negative	Negative
Histopathology	Granuloma consisting of lymphocytes, epithelioid and giant cells, small nerves completely effaced by caseating granuloma. AFB-negative	Granuloma consists of epithelioid cells and an admixture of macrophages and lymphocytes. Giant cells are also seen. Nerves replaced by granuloma. AFB may be positive or negative.	Granuloma consisting predominantly of epithelioid cells, macrophages and scattered lymphocytes. Nerve shows cut onion appearance. AFB+	Granuloma around nerve, neurovascular bundle consists primarily of macrophages and isolated clumps of epithelioid cells. Nerves show concentric perineural cell infiltration. AFB ++ including small globi	Expansive and loose granuloma with plenty of macrophages loaded with AFB. Nerves are minimally involved.

*All features can occur in various combinations as the disease progresses.
AFB = acid fast bacilli.

in the vicinity of a lesion. Skin lesions may appear at any site on the skin, but with a predilection for body parts not covered by clothing.

Borderline Tuberculoid Leprosy

Borderline tuberculoid leprosy disease spans the spectrum between the tuberculoid and lepromatous poles. It is the most important part of the spectrum in terms of number of patients, frequency, severity of reactions, and nerve damage. Patients with borderline disease suffer most of the disabilities and deformities seen in leprosy. The skin lesions resemble those of tuberculoid leprosy, but the disease is not fully contained. Individual lesions do not show the well-defined margins, and their borders may start sloping outward and even fade imperceptibly into the normal skin. Lesions may have small extensions at one edge (pseudopodium), or satellite lesions may be seen. The number of lesions may vary from 3 to 10, with variation in size and contour. The lesions tend to be large and can even cover an entire limb. The lesions have sensory loss, dryness, and scaling, with erythema or hypopigmentation (Fig. 301-1). Several peripheral nerves are likely to be enlarged in an asymmetrical pattern. Nerve damage with anesthesia or a motor deficit is often found at the time of presentation and can progress to nerve damage, paralysis, and deformity. Some untreated patients with repeated reactions deteriorate to borderline borderline or lepromatous leprosy.

Borderline Borderline Leprosy

Borderline borderline leprosy is an immunologically unstable, short-lived form of the disease that, if left untreated, mostly progresses towards the lepromatous form. Characteristic skin lesions are annular, with the inner edge well-demarcated (punched out) and the outer edge ill-defined and sloping towards normal skin. Clinically normal-looking skin within such plaques gives a "Swiss cheese" appearance (Fig. 301-2 and E-Fig. 301-2). The face may be infiltrated with occasional nodules over the ears and chin.

Borderline Lepromatous Leprosy

Borderline lepromatous leprosy manifests with numerous skin lesions, classically distinct but not so well defined. Lesions occur as slightly infiltrated, round or oval macules with a copper hue. Lesions are 2 to 3 cm in diameter, often symmetrical, and with areas of apparently normal skin in between (Fig. 301-3 and see E-Fig. 301-2). As the disease progresses, papules, nodules, and plaques may develop, with sloping margins that merge imperceptibly into normal skin. Eyebrows are either not involved or are partially lost. Skin smears show a moderate number of bacilli in the majority of the lesions. Peripheral nerve trunks become thickened at the sites of predilection, with corresponding asymmetrical anesthesia and paresis.

FIGURE 301-1. Borderline tuberculoid leprosy. A large well-defined, hypopigmented, infiltrated patch with xerosis, wrinkling of skin, loss of hairs, and pseudopodia.

Lepromatous Leprosy

Early lesions of lepromatous leprosy are innumerable small macules that are widely disseminated and distributed symmetrically. Although the infiltration initially may

E-FIGURE 301-2. Type 1 reaction in borderline tuberculoid leprosy. The existing lesion on forehead has become erythematous, edematous and shiny.

FIGURE 301-2. Annular lesions of borderline borderline leprosy. The inner edge is well demarcated and "punched out," and the outer edge is ill-defined and slopes towards normal skin.

FIGURE 301-3. Borderline lepromatous leprosy. Multiple small, hypopigmented to coppery colored infiltrated macules tending to coalesce distributed symmetrically on back.

FIGURE 301-4. Lepromatous leprosy. Diffuse infiltration of the face with edematous, waxy look with partial madarosis and few papulonodular lesions on the chin.

not be very apparent clinically, these macules are found to be slightly infiltrated; their edges are indistinct, merging imperceptibly into the normal skin. The surface of the lesion is shiny and erythematous, rather than hypopigmented. Insidious onset and steady progression may allow the disease to advance for years before a shiny, waxy appearance is recognized. Lepromatous leprosy with infiltrated lesions presents as diffuse, infiltrated, or nodular forms (Figs. 301-4 to 301-6). The sensory loss is symmetrical, usually first detected over the forearms, legs, hands, and feet. Sensory loss gradually progresses in the typical stocking and glove distribution, and autonomic dysfunction (Chapter 386) can occur.[12] Weakness usually starts early in the intrinsic muscles of the hands and feet, possibly because of direct bacillary invasion as well as involvement of the peripheral nerves. Anosmia, nasal crusting or bleeding, and nasal septal perforation occur in up to 40% of patients in long-standing disease. Eye involvement[13] includes partial to complete loss of eyebrows, often associated with corneal anesthesia owing to bacillary infiltration of the corneal nerves and later from damage to the ophthalmic division of the trigeminal nerve. Other ocular manifestations in advanced disease include lagophthalmos, corneal ulceration, perforation, corneal opacity, uveitis, and even blindness.

Reactions

Leprosy reactions are immunologically mediated episodes of acute or subacute inflammation that affect predominantly the skin and nerves. Leprosy reactions are important causes of nerve damage and, unless promptly treated, can result in deformity and disability.

Type 1 Reactions

Type 1 reaction is a delayed hypersensitivity reaction associated with sudden alteration of cell-mediated immunity, sometimes associated with a shift in the patient's position in the leprosy spectrum of disease. Type 1 reactions are mostly observed in the borderline disease spectrum. Some or all of the preexisting skin patches or plaques become erythematous and swollen, and they may become tender and mimic erysipelas. Necrosis and ulceration can occur in severe cases (E-Fig. 301-3). Crops of inflamed skin lesions in the form of plaques may appear in areas where skin was previously clinically uninvolved. Edema of extremities or face is frequent. Rapid swelling, with severe pain and tenderness of one or more peripheral nerves, commonly occurs close to the inflamed skin lesion or situated below the inflamed lesion. In severe forms, nerve abscesses may form.

Type 2 Reactions

Type 2 reaction, popularly known as erythema nodosum leprosum, is a multisystem immune-mediated reaction noted in lepromatous leprosy and borderline lepromatous leprosy disease. The reaction is characterized by the eruption of tender skin lesions accompanied by constitutional signs and symptoms. Erythema nodosum leprosum lesions appear as crops of evanescent (persisting for few days), pink (rose) tender papules, nodules, or plaques, which are variable in size. Lesions tend to be warm, painful, and tender to touch, and they blanch with light finger pressure. New erythema nodosum leprosum lesions appear as old lesions subside. An individual lesion typically changes color from pink/red to bluish and brownish over 24 to 48 hours and finally becomes dark after a week or 10 days. Lesions subside with desquamation or peeling of the superficial skin. Erythema nodosum leprosum lesions also may become vesicular, pustular, bullous, and

E-FIGURE 301-3. **Type 1 reaction in borderline tuberculoid leprosy on the face.** Erythema and edema of pre-existing lesions are evident. Ulceration of plaques, as seen in this case, is a feature of severe type 1 reaction.

FIGURE 301-5. Lepromatous leprosy. Classic earlobe nodules along with diffuse infiltration of the face. The lesions are shiny and succulent in consistency. The greater auricular nerve can be seen as a thickened cord-like structure.

FIGURE 301-6. Lepromatous leprosy. Nodular lesions over the face along with madarosis. Slit-skin smears are usually highly positive in such cases.

necrotic; they also can break down to produce ulceration called erythema nodosum necroticans (E-Fig. 301-4). Neuritis, which is the most common extracutaneous manifestation of type 2 reaction, may be acute, recurrent, or chronic. Associated features may include lymphadenopathy, myositis, arthritis, dactylitis, synovitis, laryngitis, iridocyclitis, epididymo-orchitis, and nephritis.

Other Clinical Variants

Lucio Phenomenon and Lucio Leprosy

Lucio leprosy is commonly seen in Mexico and Costa Rica, not infrequently in the Gulf coast, but quite rarely in other parts of the world. The disease, which develops in the untreated diffuse form of lepromatous leprosy, is often unmasked by a specific severe reactional state, termed the Lucio phenomenon, which occurs in patients who have no previous evidence of discrete lesions. Endothelial cell injury is the main pathogenetic event. Lucio phenomenon presents as multiple, well-defined, angular, jagged purpuric lesions, which evolve into massive ulcerations that spread in a characteristic ascending fashion over the extremities and heal with atrophic scarring. The skin looks waxy and has a shiny appearance (lepra bonita, beautiful leprosy), with obvious diffuse infiltration of the ear lobes and forehead, loss of eyebrows and sometimes eyelashes, and not infrequently all body hair. The voice may be hoarse, and numbness and edema of the hands and feet may mimic what is observed in myxedema. Unlike erythema nodosum leprosum, patients have no nodules, lymphadenopathy, or arthritis.

Histoid Leprosy

Histoid leprosy is a rarely reported entity. Clinically, the histoid lesions commonly appear as smooth, shiny, hemispherical, dome-shaped, nontender soft to firm nodules, which may be superficial, subcutaneous, or fixed deeply under the skin, accompanied by plaques or pads appearing on otherwise normal-looking skin (Fig. 301-7). The number of lesions may vary from a few to a hundred. Lesions are usually located on the face, back, buttocks, extremities, and over bony prominences, especially around the elbows and knees. Histopathologically, the striking feature is predominance of spindle- shaped cells and unusually large numbers of acid-fast bacilli. Because lesions of histoid leprosy may mimic many dermatologic conditions, diagnosis requires a high index of suspicion. Histoid patients with a high bacillary load may serve as reservoirs of infection and continue to transmit infection, so early diagnosis and treatment is essential.

Pure Neuritic Leprosy

Pure neuritic leprosy is characterized by sensory loss along the distribution of an involved nerve trunk, with or without motor deficit, in the absence of any skin lesions. Neuritic leprosy is seen more frequently in India and Nepal, where it accounts for 5 to 10% of all patients with leprosy. The nerve involvement, which may range from single to multiple, is generally asymmetrical. Up to one-third of patients may later develop skin lesions, thereby implying that a neuritic phase often precedes the development of cutaneous lesions.

Systemic Involvement

Features of systemic involvement, which usually occur in long-standing disease, are seen mainly in patients near the lepromatous pole of the spectrum of disease. Systemic involvement is due to bacillary deposits and associated granulomatous infiltration affecting various organs, especially the nasal mucosa, larynx, eyes, bones, testes, kidneys, lymph nodes, liver, and spleen. Systemic manifestations also include constitutional symptoms such as fever, malaise, joint pains, and acute inflammation of eyes, joints, reticuloendothelial system as a part of an erythema nodosum leprosum (type 2 reaction). In the era of declining leprosy prevalence and expertise, some patients with systemic symptoms may go undiagnosed for many months until astute clinical assessment raises suspicion and leads to confirmatory diagnostic testing.

Leprosy in Immunocompromised Hosts

Unlike other mycobacterial diseases, the course of leprosy is not markedly modified by the HIV infection. However, the immune reconstitution inflammatory syndrome (Chapter 358) following initiation of highly active antiretroviral therapy can develop in patients with leprosy–HIV coinfection when immunity is restored. Clinically, the immune reconstitution inflammatory syndrome usually presents as a type 1 reaction with the development of erythematous, edematous skin lesions that may ulcerate, as well as neuritis with nerve paresis and paralysis.

Leprosy has been reported in recipients of kidney, heart, lung, and bone marrow transplants, and it should be considered in the differential diagnosis of skin manifestations in organ transplant patients. Post-transplantation, multibacillary forms of leprosy predominate. The consequences of coinfection with leprosy and the SARS-CoV-2 infection are uncertain.

Leprosy and Pregnancy

In contrast to the frequent involvement of the testes in lepromatous disease, the female reproductive organs are not significantly involved in leprosy. Because of suppression of cell-mediated immunity during pregnancy and its recovery postpartum, leprosy becomes more active during pregnancy and lactation. Pregnant women can experience relapse, reactivation, and transient exacerbation of the neuropathy, as well as reversal despite multidrug therapy.

E-FIGURE 301-4. Erythema nodosum leprosum. Multiple erythematous tender nodules in varying stages of evolution over the trunk in a case of lepromatous leprosy. Note gynecomastia and wrinkling of skin in long-standing disease.

FIGURE 301-7. Histoid leprosy. Skin-colored, smooth, waxy cutaneous nodules, some with umbilication with an apparently normal appearing intervening skin. In some places, nodules coalesce to form an annular pattern.

DIAGNOSIS

A thorough history and clinical examination is essential for diagnosis. Morphologic details of the skin lesions, the extent of peripheral nerve involvement, areas of sensory loss, and systemic involvement allow the clinician to assess the patient's spectrum of disease, to individualize therapeutic decisions, and to assess the risk of complications that the patient may face during the course of illness and treatment.[14] The physical examination should specifically focus on a careful cutaneous and mucosal examination to identify the type and number of skin lesions; evaluation of peripheral and cranial nerves; and testing for sensory and motor impairment. Pregnancy should be determined in women of childbearing age because some medications used to treat leprosy may be contraindicated in such settings.

Laboratory Testing

Although an expert physician can identify most patients by clinical examination alone, laboratory testing plays an important role in early diagnosis as well as in monitoring the response to treatment. Slit-skin smear examination, which is the most simple and valuable test,[15] helps to confirm the diagnosis, classify the spectrum of disease, and determine its activity. The number of acid-fast bacteria in each field is counted and graded from zero to 6+ as the bacteriologic index.

The morphology of the bacilli should be carefully examined to determine the percentage of *M. leprae* that are alive or dead, termed the morphologic index. Solid stained bacilli are live and viable, whereas the granular, broken, and fragmented bacilli are dead and nonviable.

Skin biopsy at an active, infiltrated edge of the most active lesion can confirm the diagnosis and type of leprosy, as well as identify type 1 and type 2 reactions, but leprosy is often a clinical diagnosis in endemic countries. Fine needle aspiration cytology can diagnose neuritic leprosy with increased sensitivity when it is combined with multiplex polymerase chain reaction (PCR) testing. Rapid molecular assays for detection of *M. leprae,* such as PCR-based techniques, have a specificity of 100% and a sensitivity ranging from 34 to 80% in the paucibacillary form of leprosy but a sensitivity greater than 90% in the multibacillary form. RNA analysis using 16 S rRNA and reverse-transcription PCR has the added benefit of measuring the viability of *M. leprae*.[16] Nerve biopsies can confirm the diagnosis of leprosy, especially in patients who present with pure neuritic leprosy without skin lesions[17]; a thickened sensory nerve, such as the radial cutaneous nerve at the wrist or the sural nerve at the back of the leg, is preferred for biopsy.

Diagnostic Criteria

The diagnosis of leprosy is established by finding at least one of the following cardinal signs: 1) definite loss of sensation in a pale (hypopigmented) or reddish skin patch; 2) thickened or enlarged peripheral nerve, with loss of sensation and/or weakness of the muscles supplied by that nerve; and 3) presence of acid-fast bacilli in a slit-skin smear. The sensitivity and specificity of each one of these signs is high, but the most important potential source of error is inter-observer variation in the examination of an individual patient and reading of the skin smears.

TREATMENT

Multidrug Chemotherapy

Multidrug therapy, which consists of rifampicin, dapsone, and clofazimine (Table 301-3),[18–20] is highly successful for curing all forms of leprosy.[A1] The duration of treatment is 6 months for paucibacillary leprosy and 12 months for multibacillary leprosy. In general, leprosy and lepra reactions respond equally well even in immunosuppressed patients.

Rifampicin may color bodily secretions (tears, urine, etc.) red or orange. Gastrointestinal side effects include epigastric distress, nausea, vomiting and diarrhea. The most important adverse effect is hepatitis, which is usually not serious, unless compounded by another drug that also affects the liver. Rare but significant side effects include a flu-like syndrome, renal failure, and thrombocytopenia, particularly with intermittent therapy. Rifampicin also induces liver enzymes, so some other drugs (e.g., oral contraceptives) may be rendered less effective because they are metabolized more quickly. Clofazimine causes orange-brown discoloration and darkening of the skin, mucosa, cornea, and body fluids, but the discoloration is generally reversible after the drug is stopped. At high doses, clofazimine builds up in the tissues and can precipitate to form crystals, especially in the intestinal mucosa (crystal enteropathy), lymph nodes, and in fatty tissue. The formation of crystals in the gastrointestinal tract may lead to abdominal pain, nausea, and diarrhea, which, although rare, may be fatal in severe cases. Splenic infarction, eosinophilic enteritis, and cardiac arrhythmias also have been reported. Dapsone's adverse effects include anemia and methemoglobinemia. An insignificant degree of hemolysis occurs in virtually every patient but may be of clinical concern in patients with glucose-6-phosphate deficiency (Chapter 147). Dapsone hypersensitivity syndrome, which generally manifests by 4 to 6 weeks after starting dapsone, is a rare but sometimes fatal complication characterized by fever, skin rashes (ranging from a maculopapular eruption to toxic epidermal necrolysis), generalized lymphadenopathy, hepatitis, and hepatosplenomegaly.

Leprosy Drug Resistance

Resistance to triple therapy, though unusual, has been reported in several countries. Patients whose infection is resistant to rifampicin should be treated using at least two of the following second-line drugs: clarithromycin 500 mg daily), minocycline (100 mg daily), or a quinolone (e.g., ofloxacin [400 mg daily], levofloxacin [500 mg daily], or moxifloxacin [400 mg daily]) plus clofazimine (50 mg daily) for 6 months, followed by clofazimine plus one of the second-line drugs daily for an additional 18 months. When ofloxacin resistance is also present, a fluoroquinolone should not be used as part of second-line treatment. The regimen of choice in such cases should be 6 months of clarithromycin, minocycline, and clofazimine followed by clofazimine plus either clarithromycin or minocycline for an additional 18 months.

Immunotherapy

Mycobacterium indicus pranii, which is a rapidly growing, nonpathogenic, cultivable mycobacterium that shares several antigens with *M. leprae*, is administered intradermally as a killed vaccine (0.1 mL in two equally divided doses on both the arms) and repeated every 3 to 6 months until the end of treatment). Adding this immunotherapy, particularly in highly infected patients, can result in more rapid bacterial clearance, an earlier achievement of smear negativity, and more rapid clearance of skin lesions on histopathology in a significantly higher percentage of patients.[21] Topical insulin may be helpful to promote healing of trophic skin ulcers,[A2] but other local therapies have been disappointing.[A3]

Treatment of Reactions

The goals of treating reactions are to control the skin and nerve inflammation, relieve pain, prevent further episodes of reaction, reduce morbidity, and prevent deformities. For mild type 1 reactions, standard doses of a nonsteroidal anti-inflammatory drug (e.g., aspirin, indomethacin, ibuprofen, diclofenac, or acetaminophen [see Table 26-4) should be given for several weeks. Reassurance is very important to the patient as well as to family members. For moderate to severe type 1 reactions, prednisolone (between 0.5 and 1.0 mg/kg of body weight/day, equivalent to 30 or 40 mg daily for most adults) is given orally for 20 weeks.[A4] In patients who do not respond to steroids or who experience steroid-related adverse effects, alternative treatments under expert care have included systemic methotrexate, cyclosporine, azathioprine, mycophenolate mofetil, and topical tacrolimus. In the acute phase, the inflamed nerves must be kept in a resting position; appropriate splinting and padding give relief. Surgical nerve decompression may sometimes be indicated to relieve persistent increased intraneural pressure, tenderness, and acute inflammation if they lead to ischemia in the nerve.

TABLE 301-3 RECOMMENDED ORAL MULTIDRUG THERAPY

AGE	DRUG	DOSAGE & FREQUENCY	DURATION	
			MULTIBACILLARY	*PAUCIBACILLARY*
Adult	Rifampicin Clofazimine Dapsone	600 mg once a month 300 mg once a month and 50 mg daily 100 mg daily	12 mo	6 mo
Children (10-14 yr)	Rifampicin Clofazimine Dapsone	450 mg once a month 150 mg once a month and 50 mg on alternate days 50 mg daily	12 mo	6 mo
Children (<10 yr old or <40 kg)	Rifampicin Clofazimine Dapsone	10 mg/kg once a month 100 mg once a month and 50 mg twice weekly 2 mg/kg/daily	12 mo	6 mo

Data from World Health Organization. *Guidelines for the Diagnosis, Treatment and Prevention of Leprosy*. Geneva: World Health Organization; 2018.

Mild type 2 reactions can be managed with anti-inflammatory drugs and analgesics, as for type 1 reactions, but some patients may respond to tramadol (50 to 400 mg/day) or colchicine (0.5 mg up to three times daily with a tapering course). Aspirin can be given at a dose as high as 600 mg every 6 hours with meals (up to a maximum dose of 2.8 g/day), with the dose reduced slowly as signs and symptoms are controlled. For severe type 2 reactions, oral corticosteroids (prednisolone not exceeding 1 mg/kg of body weight/day for a total duration of 12 weeks) rapidly control inflammation and relieve pain; the dose should be tapered rapidly to the lowest dose required to keep the reaction under control. For corticosteroid-dependent, nonresponsive, chronic, or recurrent cases, clofazimine should be given as 300 mg daily for 1 month, followed by 200 mg daily for 3 to 6 months, followed by 100 mg daily for as long as the erythema nodosum leprosum symptoms remain. At this high dose, the drug often worsens the reddish-brown skin pigmentation (reversible over 4 to 6 months of stopping) and increases the risk of clofazimine-induced crystal enteropathy and cardiotoxicity. Thalidomide (started at a dose of 400 mg daily; 200 mg twice or 100 mg four times daily) is also effective for men and postmenopausal women with severe type 2 reactions and difficult-to-manage erythema nodosum leprosum,[22] steroid-dependent patients, and patients in whom steroids are contraindicated; however, thalidomide is a second-line option because of its teratogenicity, cost, and limited availability. Thalidomide typically controls the reaction within 3 to 7 days, at which time the dose should then be tapered to 300 mg (100 mg in the morning and 200 mg in the evening daily) over 4 weeks, followed by a 100-mg dose reduction each month. If thalidomide is used in women of childbearing age, successful contraception is critical. Alternative therapies occasionally tried for type 2 reactions under expert care include pentoxifylline, azathioprine, cyclosporine, mycophenolate mofetil, immunotherapy, zinc, minocycline, anti–TNF-α agents (e.g., infliximab, etanercept, adalimumab), leukotriene inhibitors, and apremilast and thalidomide derivatives.

Leprosy and Pregnancy

Leprosy treatment should be continued unchanged during pregnancy and breast-feeding, except that thalidomide, methotrexate, azathioprine, cyclosporine, apremilast are contraindicated during pregnancy. Cases of dapsone-induced hemolytic anemia have been reported in mothers and their babies, with symptoms resolving after discontinuing dapsone. Oral corticosteroids (see above) are the preferred anti-reaction drugs in pregnancy.

PREVENTION

Leprosy probably cannot be eliminated by the successful treatment of infected individuals, and no vaccine is currently available. Single-dose rifampicin (Table 301-4)[23] treatment of adults and children ages 2 years and above who are contacts (defined as a person who has been living, working, or having social activities for more than 3 months and 20 hours per week with a newly detected case of leprosy in the last year) of patients who have leprosy reduces the risk of leprosy by 57% at 2 years and by 30% after 5 to 6 years. This intervention should be implemented only by programs that can ensure adequate management of contacts and consent of the index case to disclose his/her disease. Contacts who are found to have leprosy or tuberculosis (Chapter 299) require full treatment for active disease.

Bacillus Calmette-Guérin (BCG) vaccine at birth is effective in reducing the risk of leprosy,[24] so its use should be continued in all high-burden countries or settings. BCG vaccine at birth also appears to potentiate the protective effect of single dose rifampicin in contacts from 57% to 80%.[A5] Data are insufficient to recommend BCG vaccination of contacts.[A6] Moderate-quality evidence indicates the efficacy of vaccination using *Mycobacterium indicum pranii* in preventing leprosy.[25]

TABLE 301-4 SINGLE-DOSE RIFAMPICIN

AGE/WEIGHT	RIFAMPICIN SINGLE DOSE
15 yr and above	600 mg
10-14 yr	450 mg
Children 6-9 yr (weight ≥20 kg)	300 mg
Children <20 kg (≥2 yr)	10-15 mg/kg

Data from World Health Organization. *Guidelines for the Diagnosis, Treatment and Prevention of Leprosy*. Geneva: World Health Organization; 2018.

Global Strategies

The Global Partnership for Zero Leprosy aims to reduce the burden of disease by about 70% to fewer than about 63,000 cases worldwide. To achieve the goal, effective diagnostics for early detection, newer therapies, and vaccines likely will have to be combined with programs that address social and environmental factors.

PROGNOSIS

Untreated tuberculoid leprosy may sometimes remit, but multibacillary leprosy is always progressive with devastating consequences for the patients and the risk of spreading infection in community. Multidrug chemotherapy cures most patients, but sequelae such as drug reactions, neuropathic pain, and trophic ulcers may persist after treatment. Relapse rates are reported to be about 0.1% per year in paucibacillary leprosy but can be as high as 5% per year in multibacillary leprosy, particularly in patients who have a high bacteriologic index at baseline.[26]

302 RICKETTSIAL INFECTIONS

PIERRE-EDOUARD FOURNIER AND DIDIER RAOULT

DEFINITION

Rickettsial diseases are emerging infectious diseases.[1] Because of better diagnostic tools, increased awareness, and changes in tick exposure, new rickettsial diseases continue to be described in recent years. Three families of diseases are grouped under rickettsioses: ehrlichioses and anaplasmoses and Q fever (Table 302-1).

The Pathogens

The agents of rickettsial diseases are small, gram-negative, intracellular bacteria that are associated with eukaryotic cells. Except for *Coxiella burnetii*, which is the agent of Q fever, they have not yet been grown in axenic media, but rather require living hosts (e.g., cell cultures, embryonated eggs, or susceptible animals) for growth. With the exception of *Rickettsia prowazekii*, which is the agent of epidemic typhus and which is specifically associated with the human body louse, these bacteria infect humans incidentally and are mainly animal pathogens. Polymerase chain reaction (PCR) amplification of DNA from blood samples, biopsy specimens, and cutaneous eschar swabs has helped identify new species.

RICKETTSIOSES (DISEASES CAUSED BY *RICKETTSIA* SPECIES AND *ORIENTIA TSUTSUGAMUSHI*)

PATHOBIOLOGY

Rickettsia spp are small gram-negative bacteria that multiply freely in the cytoplasm of their host cells. The genome of *Rickettsia* is small, between 1.1 and 1.6 Mb; some have plasmids and potential for conjugation. These bacteria have a family of outer membrane proteins of the surface cell antigen family, including rOmpA (lacking in the typhus group) and rOmpB. These proteins are major antigens that help identify the rickettsial species by serology, and their encoding genes are used for amplification and sequencing for diagnostic or taxonomic purposes. Complete genome sequencing of *Rickettsia* species demonstrates that these bacteria are undergoing a genomic reduction process as a result of various phenomena, including progressive gene degradation and genomic rearrangements and also a paradoxical expansion of small RNAs and short palindromic elements.[2] Genome sequence–based taxonomic information can reliably classify rickettsial isolates at the genus and species levels.[3]

The target cells in humans are vascular endothelial cells or monocytes, and vasculitis is the most prominent result. These bacteria invade cells by phagocytosis and escape the phagosome vacuole.

TICK-BORNE RICKETTSIOSES

ROCKY MOUNTAIN SPOTTED FEVER

EPIDEMIOLOGY AND PATHOBIOLOGY

Rocky Mountain spotted fever (RMSF), which is the most severe of tick-borne rickettsioses, is caused by *Rickettsia rickettsii* (Table 302-2). Rocky Mountain spotted fever is the major tick-borne rickettsiosis recognized in America[4] and is prevalent in at least 44 states in the United States (Fig. 302-1)[5] as well as in Central and South America (Argentina, Brazil, Colombia, Costa Rica, Mexico, and Panama).

In ticks, *R. rickettsii* is transmitted transovarially from one generation to the next. The infecting ticks are mainly *Dermacentor andersoni* (a wood tick) in the Western United States; *Dermacentor variabilis* (the American dog tick) in the East, the Midwest, and the South; and *Rhipicephalus sanguineus* in Arizona. In Central and South America, *Amblyomma cajennense* is the major vector. Humans are infected through infected saliva after a tick bite. The duration of attachment is critical in any tick-borne rickettsiosis. Transmission is unlikely when the tick feeds for less than 20 hours.[6] Since the tick bite is painless, it is often unnoticed. An eschar at the tick bite site is rarely observed. The epidemiology of Rocky Mountain spotted fever varies annually. This temporal repartition is determined by tick activity and human encounters. More than 500 cases occur each year, and more than 90% are reported from April to September. The disease is more common in children under 10 years of age.

CLINICAL MANIFESTATIONS

Two days to two weeks after the tick bite, fever and headaches appear. The fever is high (temperature >102°F) and associated with nonspecific symptoms such as malaise, myalgias, nausea, vomiting, anorexia, and diarrhea. Due to the absence of specific symptoms, Rocky Mountain spotted fever is not frequently diagnosed at this stage, but patients with high fever who live in or have a history of travel to an endemic area during the "tick season" and, possibly, have a history of tick bite should be considered as possible cases of Rocky Mountain spotted fever.

The most characteristic feature is a rash. However, the classic triad of fever, headache, and rash is present in only 44% of confirmed cases. A rash is found in 14% of cases on the first day of disease and in less than 50% in the first 3 days. The rash is macular; spots are 1 to 5 mm in diameter and can evolve from pink to purpuric (Fig. 302-2). The rash appears first on the ankles and wrists and then generalizes, but it can appear later or even not at all. Involvement of the palms and soles theoretically differentiates the typhus diseases (in which it is absent) from spotted fever rickettsioses. "Spotless" Rocky Mountain spotted fever represents one-third of cases.

Untreated patients worsen progressively. The disease is associated in various degrees with general manifestations related to vascular inflammation and increased vascular permeability, which can lead to multiple organ dysfunction syndrome. In severe forms, patients suffer from edema, hypovolemia, hypoalbuminemia, and hypotension leading to shock. In very severe cases, necrosis and gangrene of the extremities occur. In some instances, noncardiogenic pulmonary edema develops; pulmonary involvement leading to respiratory distress can cause death. Renal failure can result either from hypovolemia and shock and be reversible or from acute tubular necrosis and require hemodialysis. The usual neurologic symptoms are confusion, lethargy, and stupor. In severe cases, delirium, coma, and seizures are observed.[7] In some series, cerebrospinal fluid (CSF) sampling exhibits meningitis in one third of cases; in general, a few mononuclear cells (10 to 100) are observed, along with increased protein but normal glucose levels. Cardiac arrhythmias may occur. Intestinal tract involvement is manifested as abdominal pain, diarrhea, vomiting, and severe bleeding. Upper gastrointestinal hemorrhage can cause death. Ocular involvement may consist of conjunctivitis and retinal abnormalities, including hemorrhages, papilledema, and arterial occlusion.

The white blood cell count is usually normal, but immature myeloid cells are frequently present. Thrombocytopenia is observed in 30 to 50% of cases and may be marked in severe cases. Anemia develops in 30% of patients. Coagulopathy with decreased clotting factors (including fibrinogen) and prolonged coagulation times may contribute to bleeding. There may be hypoalbuminemia, and proteins of the acute phase response are increased (C-reactive protein, ferritin, fibrinogen). Hyponatremia and hypocalcemia may be noted and correlate with severity, as does an increase in creatinine. Increased concentrations of serum liver and muscle enzymes such as aminotransferases (aspartate [AST] and alanine [ALT] aminotransferase), lactate dehydrogenase (LDH), and creatine kinase usually reflect the severity of organ involvement, including the lung, heart, liver, and rhabdomyolysis.

DIAGNOSIS

The diagnosis of Rocky Mountain spotted fever should rely on clinical and epidemiologic findings. The most important clue is unexplained fever in a patient with a history of tick exposure in an endemic area. When a rash is present, Rocky Mountain spotted fever should be suspected and the patient should be treated accordingly unless another cause is demonstrated.

The differential diagnoses include other rickettsioses (such as those caused by *R. parkeri* in southern states), meningococcemia (Chapter 274), enterovirus infections (Chapter 349), typhoid (Chapter 284), leptospirosis (Chapter 298), ehrlichiosis, gonococcemia (Chapter 275), toxic shock syndrome (Chapters 267 and 269), syphilis (Chapter 295), rubella (Chapter 339), measles (Chapter 338), and Kawasaki syndrome (Chapters 254 and 406). Drug hypersensitivity (Chapter 234), especially after antimicrobial use for febrile illness, is sometimes confused with Rocky Mountain spotted fever.

Direct detection of the bacterium by demonstration of specific antigens by immunodetection or genomic amplification by PCR provides a definite diagnosis of infection.[8] A biopsy specimen or a swab of a skin lesion, preferably of an inoculation eschar, is the best sample for this purpose. Direct detection in removed ticks using PCR is also very useful. In contrast, blood contains inhibitors and only a few copies of rickettsial DNA.

ABSTRACT

Rickettsioses, which include infections that are mostly arthropod-borne and zoonotic, are caused by *Rickettsia* sp, *Ehrlichia* sp, or *Coxiella burnetii*. These infections are encountered worldwide, and their distribution mimics that of their reservoirs and/or vectors. Rickettsioses represent a heavy disease burden in both farm animals and humans and are among the main causes of travel-associated infections. They may be difficult to diagnose because most patients will present with mild symptoms, but some of the rickettsioses, such as Mediterranean spotted fever, have a characteristic clinical picture. Epidemic typhus and Rocky Mountain spotted fever are associated with significant mortality.

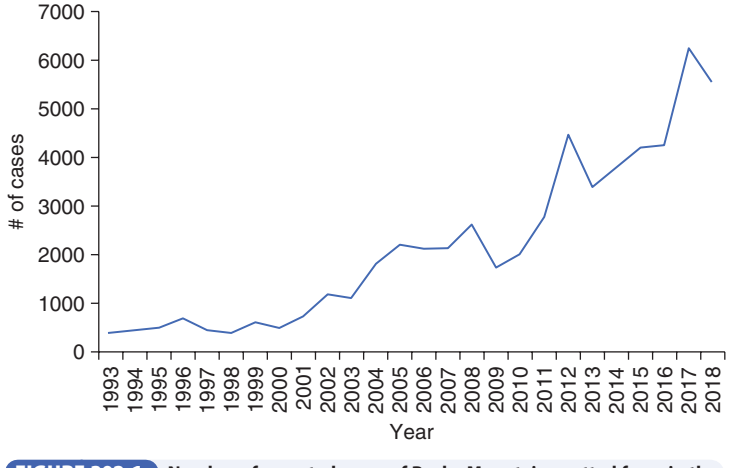

FIGURE 302-1. Number of reported cases of Rocky Mountain spotted fever in the United States, 1993 to 2018.

The diagnosis can also be confirmed by serology, but treatment should never be delayed to obtain its results. Criteria for laboratory confirmation include a four-fold or greater change in antibody titer determined by serology (measured by immunofluorescence antibody assay). Two serum samples should be tested (early and convalescent). The early serum is usually negative because patients seroconvert between the 7th and 15th days. A cutoff value of 1:64 for total immunoglobulin and 1:32 for IgM antibodies is required for diagnosis. The latex agglutination cutoff is 1:64 or 1:128.

However, serology is nonspecific. Cross-reactive antibodies have been reported, mainly with infections caused by other rickettsioses, but also infections with *Ehrlichia, Bartonella, Legionella*, and *Proteus* spp. False-positive results, including IgM, may be observed when rheumatoid factor is present in serum and in patients who have viral infections that generate nonspecific B-lymphocyte proliferation (e.g., cytomegalovirus [Chapter 347], Epstein-Barr virus [Chapter 348]).

Culture of rickettsiae takes 3 to 7 days and is restricted to specialized laboratories. Immunodetection by immunofluorescence antibody assay or immunohistochemistry is sensitive and specific but requires specific antibodies. It

FIGURE 302-2. Rocky Mountain spotted fever. Maculopapular rash observed in a patient with Rocky Mountain spotted fever. (Courtesy Gerardo Alvarez, MD, University of Sonora, Mexico.)

can be performed with frozen or fixed and paraffin-embedded material and allows retrospective diagnosis.

TREATMENT

Doxycycline is life-saving in patients with Rocky Mountain spotted fever,[9] and the prognosis depends on the timing of antimicrobial treatment. The recommended dose is 100 mg two times a day, and treatment should be continued for at least 3 days after the fever resolves. Oral treatment is effective, but the intravenous route should be used in patients with gastric intolerance or coma. Fluoroquinolones, rifampin, and some macrolides (azithromycin and clarithromycin but not erythromycin) are also effective in vitro, but lack of clinical experience precludes their use for Rocky Mountain spotted fever. β-Lactam antimicrobials, aminoglycosides, and cotrimoxazole are not effective.

Severely ill patients should be treated in intensive care units. Fluid administration must be carefully monitored. Mechanical ventilation is used in case of respiratory distress (Chapter 90), hemodialysis in patients with renal insufficiency (Chapter 117), and antiseizure drugs in patients with seizures (Chapter 372). Anemia and coagulation abnormalities may also be corrected. For patients with gangrene of the extremities, amputation may be necessary. Glucocorticoids have not proved useful.

PREVENTION

Prevention is based on the use of repellents, protective garments, or both to avoid tick bites. Repellents containing permethrin can be sprayed on boots and clothing and will persist for several days. Repellents containing DEET (*N,N*-diethyl-*m*-toluamide) can be applied to the skin but will persist only a few hours before reapplication is necessary. After being outdoors in areas of potential tick exposure, careful examination of the scalp, groin, and axillae is also recommended. The tick can be removed by forceps, and the skin should be disinfected (Fig. 302-3).

PROGNOSIS

The prognosis of Rocky Mountain spotted fever depends strongly on the timing of diagnosis and antimicrobial treatment. The overall case-fatality rate is 2.5%, but it is higher in patients older than age 70 years (9%). No significant difference in outcome has been observed between Blacks and Whites. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency are more susceptible to severe infection. Recovery is usually complete, but neurologic sequelae can remain, and amputation of extremities may be necessary after gangrene.

OTHER TICK-BORNE RICKETTSIOSES

EPIDEMIOLOGY

Tick-borne rickettsioses have a limited geographic distribution that is determined mainly by the ecology of the tick vector (Fig. 302-4). *R. parkeri* has been identified in the United States and South America. *R. philipii* is seen in the United States. In Europe, *R. conorii* is distributed around the Mediterranean and Caspian seas (*caspia* subspecies); *R. slovaca, R. raoultii*, and possibly *R. helvetica* are seen in Western and Central Europe; and *R. sibirica mongolitimonae*

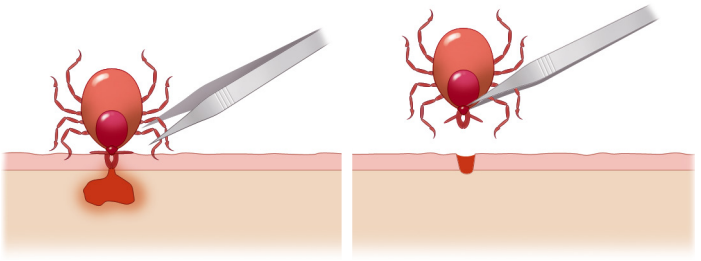

FIGURE 302-3. Tick removal technique.

is detected in France and Greece. Elsewhere, a number of specific agents of rickettsial disease have been identified (see Table 302-2).

R. africae causes African tick-bite fever, which may be the most common rickettsiosis worldwide. It is extremely common in travelers visiting safari parks in Southern Africa.[10] It is transmitted by *Amblyomma hebraeum* and *Amblyomma africanum* ticks. These ticks are often infected; as many as 60% can harbor *R. africae*. They usually feed on ungulates but also attack human beings in groups and cause a high prevalence of infection in rural Africa and in travelers. The tick attacks typically generate clusters of cases as well as multiple eschars in safari tourists.

CLINICAL MANIFESTATIONS

R. conorii comprises different but closely related subspecies. Many names are given to the infection caused by *R. conorii*: mainly Mediterranean spotted fever, but also boutonneuse fever, Marseilles fever, and Kenya tick typhus for infections caused by the subspecies *R. conorii conorii*; Astrakhan fever (caused by *R. conorii caspia*); Israeli spotted fever (caused by *R. conorii israelensis*); and Indian tick typhus (caused by *R. conorii indica*). *R. conorii* is closely related to *R. rickettsii*, with which it shares many common antigens that generate cross-reactive antibodies.

Mediterranean spotted fever resembles Rocky Mountain spotted fever but has some distinguishing features. A malignant form of the disease that includes purpuric rash, shock, and multiple organ dysfunction has been described in elderly, debilitated patients and in patients with liver disease, diabetes, human immunodeficiency virus (HIV) or G6PD deficiency. The typical clinical presentation is that of a patient with fever, a rash, and a tache noire (i.e., an inoculation eschar at the site of the tick bite). A tache noire is found in 50 to 80% of cases. Multiple eschars are rare because the dog tick vector, *R. sanguineus*, seldom bites humans. The rash is frequently maculopapular and involves the palms and soles but spares the head.

Israeli tick-bite fever and Astrakhan fever appear to be milder than typical Mediterranean spotted fever. A tache noire is usually lacking.

African tick-bite fever differs from Mediterranean spotted fever in that it is much milder. Fever is frequently absent. Rash, which is observed in only about 50% of patients, may be vesicular (which has never been reported in confirmed Mediterranean spotted fever). Moreover, several eschars are frequently observed, often on the lower limbs and associated with draining lymphadenopathy in the groin.

Japanese spotted fever (caused by *Rickettsia japonica*) and Siberian tick typhus (caused by *R. sibirica*) resemble Mediterranean spotted fever. Lymphangitis-associated rickettsiosis, caused by *R. sibirica mongolitimonae*, also resembles Mediterranean spotted fever but in some cases exhibits distinguishing clinical features, including an eschar, groin lymphadenopathy, and lymphangitis joining these two lesions. *Rickettsia australis* (Queensland tick typhus) and *Rickettsia honei* (Flinders Island spotted fever) cause diseases resembling Mediterranean spotted fever, but their rash can be vesicular.

R. slovaca and *R. raoultii* cause a common disease in Europe named scalp eschar and neck lymphadenopathy transmitted by ticks (SENLAT, reported in the Czech Republic, France, Hungary, Germany, Italy, Lithuania, Romania, Spain, Turkey). Its tick vectors, *Dermacentor marginatus* and *Dermacentor reticulatus*, preferentially bite in cold months and bite the scalp. In contrast to other tick-borne rickettsioses, the disease is more prevalent in children and women. It is rarely exanthematic; the typical clinical picture consists of an inoculation eschar at the site of the tick bite on the scalp and draining neck lymphadenopathy (which may be painful). Rarely, patients may exhibit fever and a rash. Deep postinfectious asthenia and residual alopecia at the site of the tick bite can be observed. Other *Rickettsia* species that rarely have been identified as causing SENLAT include *Rickettsia massiliae*, *Rickettsia sibirica mongolitimonae*, and *Candidatus* Rickettsia rioja.

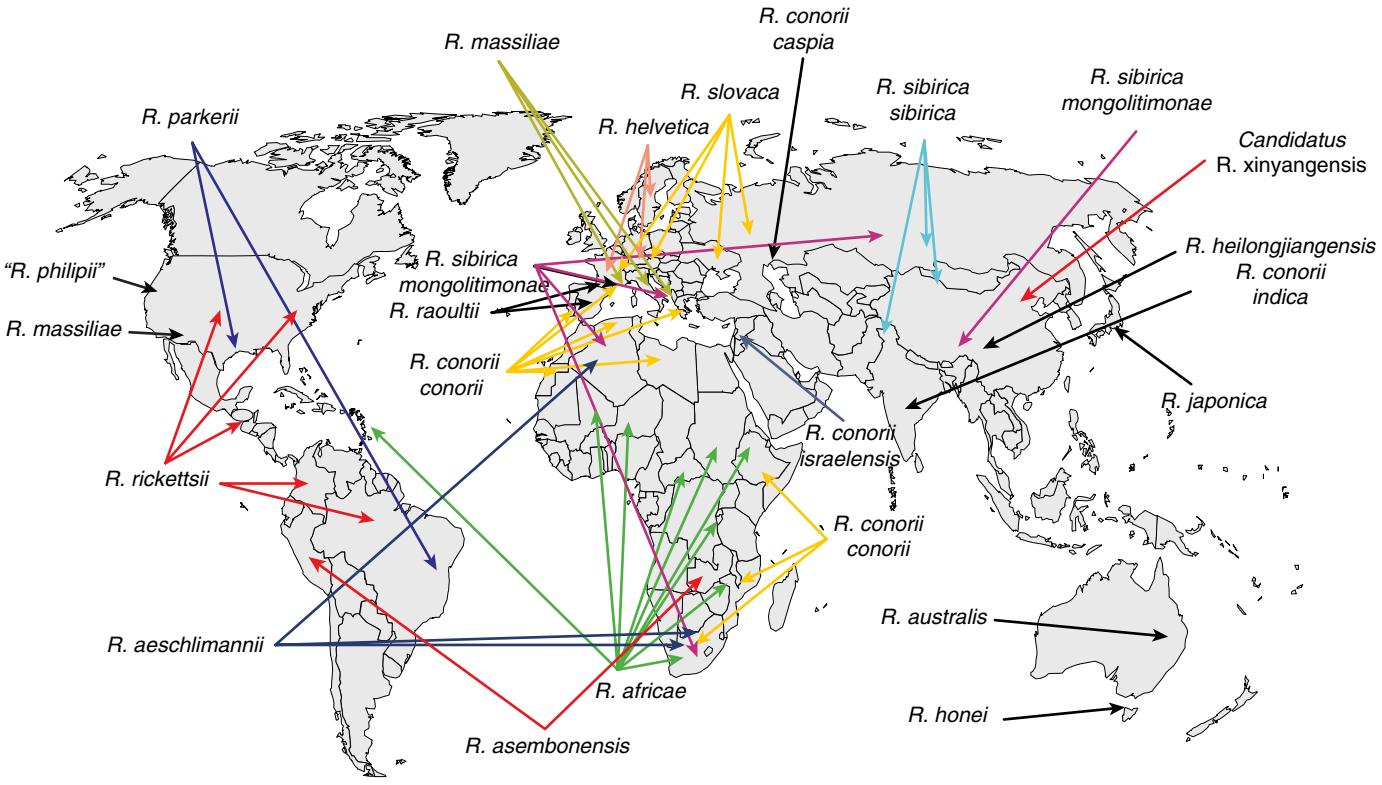

FIGURE 302-4. **Geographic distribution of tick-borne rickettsioses.**

DIAGNOSIS

The diagnosis of other tick-borne rickettsioses is similar to that of Rocky Mountain spotted fever, mainly by serology,[11] although PCR testing is becoming increasingly available.[12] An exception is *R. slovaca* infection, in which the serologic response is weak, possibly because of its lack of general infection; in this case, PCR of a skin eschar sample by a swab or a lymph node aspirate provides the highest diagnostic yield. In *R. africae* infection, the serologic response occurs later than in Rocky Mountain spotted fever and Mediterranean spotted fever; late serum samples (i.e., 4 weeks after onset of symptoms) are therefore recommended.

TREATMENT

Doxycycline (100 mg twice daily for adults or 4.4 mg/kg body weight per day in two divided doses for children under 45.4 kg [100 lb]) is the drug of choice. A single day of therapy usually suffices; in adults with more severe disease, however, it should be administered until the patient is afebrile for 24 hours. Quinolones (e.g., ciprofloxacin 1 g daily) and newer macrolides (e.g., azithromycin 500 mg daily for 5 days) provide results that are comparable to those of doxycycline but require longer treatment courses. In pregnant women, josamycin, a macrolide antimicrobial, has proved efficient at a dose of 3 g daily for 7 days for Mediterranean spotted fever.

PROGNOSIS

Most patients recover completely with treatment, but hospitalized patients have a fatality rate of 1.5 to 2.5%.

FLEA-TRANSMITTED DISEASES

Fleas (Chapter 98) can harbor three rickettsial species: *Rickettsia typhi*, which is the agent of murine typhus; *Rickettsia felis*, which is the agent of flea-borne spotted fever; and *R. asembonensis*. Both *R. typhi* and *R. felis* can be transmitted transovarially in the flea. Vectors are *Xenopsylla cheopis* and *Pulex irritans* but also *Ctenocephalides felis*, which is a cat flea. Rats, cats, opossums, and dogs can propagate infected fleas. These reservoirs and vectors are distributed worldwide, so these diseases have a global distribution. Fleas can be infected by both species at the same time. *R. asembonensis*, the agent of an unnamed rickettsiosis, has been associated with cat fleas worldwide but detected in humans only in Peru and Zambia.

MURINE TYPHUS

EPIDEMIOLOGY AND PATHOBIOLOGY

In the United States, 50 to 100 cases are reported yearly, mainly in Southern California and southern Texas.[13] In California, a transmission cycle involving opossums and cat fleas has been demonstrated. Murine typhus is extremely common in China, Southeast Asia, and North Africa, and it also is a common cause of fever in travelers to those areas.

Fleas are usually infected by *R. typhi* when feeding on apparently healthy rats that have blood-borne infection. Humans and other mammals are infected through autoinoculation by scratching a flea bite that is contaminated with feces from an infected flea. Murine typhus, because of its cycle, is more prevalent in hot and humid areas, when rats proliferate.

CLINICAL MANIFESTATIONS

The incubation period is generally 8 to 16 days. The disease begins with abrupt fever, nausea, vomiting, myalgias, arthralgias, and headache. A rash, which develops in 40 to 50% of patients about 6 days after the onset, is detected less frequently in patients with dark skin. The rash begins as pink maculae that can evolve to be maculopapular. The rash is often discrete, starting in the axilla and spreading to the trunk but not usually to the face, palms, or soles. In severe cases, it can become purpuric.

The most frequently involved organ is the lung. One third of patients have a cough, and about 25% of patients develop a nonspecific interstitial pneumonia that is sometimes associated with a pleural effusion. In severe forms, respiratory failure occurs. Digestive involvement can manifest as vomiting, abdominal pain, jaundice, and, in severe cases, hematemesis. In patients with severe disease, neurologic symptoms range from confusion and stupor to coma and seizures. Cerebral hemorrhages may occur.

The white blood cell count shows leukopenia and then leukocytosis. Thrombocytopenia can be noted as well as anemia, specifically when hemolysis is observed (frequently in patients with G6PD deficiency). A moderate increase in serum liver enzymes is common. In patients with severe disease, hyponatremia and hypoalbuminemia are observed.

DIAGNOSIS

The diagnosis of murine typhus, as with Rocky Mountain spotted fever, is based mainly on serology immunofluorescence antibody assay. *R. typhi* cross-reacts with *R. prowazekii*, but it can be differentiated by additional testing.

Skin biopsies and blood samples for culture and PCR may be valuable but cannot currently substitute for serologies.

TREATMENT

Treatment is the same as for Rocky Mountain spotted fever.

PROGNOSIS

The prognosis is usually favorable, but about 35% of patients require urgent hospital admission and 1% die.[14] Older patients and patients with G6PD deficiency (Chapter 147) or chronic debilitating conditions are at higher risk.

FLEA-BORNE SPOTTED FEVER CAUSED BY *RICKETTSIA FELIS*

In fleas, *R. felis* is mainly transmitted transovarially. Its genome comprises one or two plasmids, one being apparently conjugative. The bacterium is found in fleas in the Americas, Asia, Europe, Africa, and New Zealand. *R. felis* has been found at very high prevalence in the blood of febrile sub-Saharan Africans and is suspected to be transmitted by mosquitoes. Isolated cases have been reported from Texas, Mexico, Brazil, France, and Germany. Among reported cases, all exhibited fever, most had a rash, and an inoculation eschar was visualized in some cases. The diagnosis can be based on serologic testing using immunofluorescent assay or using PCR on blood swabs or skin biopsy samples. Treatment has not been established, but the bacterium is highly susceptible to doxycycline (as for Rocky Mountain spotted fever) and resistant to erythromycin.

LOUSE AND MITE INFECTIONS

EPIDEMIC LOUSE-BORNE TYPHUS

Epidemiology and Pathobiology

The human body louse, *Pediculus humanus humanus* (Chapter 98), lives in clothes and multiplies rapidly when cold weather and lack of hygiene permit. The body louse transmits three bacterial diseases: trench fever (caused by *Bartonella quintana* [Chapter 291]), relapsing fever (caused by *Borrelia recurrentis* [Chapter 297]), and exanthematic or epidemic typhus (caused by *R. prowazekii*). Louse-transmitted diseases killed more people than weapons did during Central and Eastern European wars in the 19th and 20th centuries. The body louse is prevalent in cold seasons during wars, in poor countries, and in the homeless population of rich countries, including the United States and Europe. Over the past 30 years, epidemic typhus has been reported in Burundi, where a 100,000-person outbreak occurred in 1997 during the civil war.

The epidemiology of *R. prowazekii* is mainly related to humans as reservoirs and lice as vectors. In the United States, the eastern flying squirrel (*Glaucomys volans volans*) is also a reservoir, and its fleas, lice, and mites can be infected and, occasionally, infect humans.

R. prowazekii has also seldom been found in *Amblyomma* ticks, but their role in the epidemiology of the bacterium is unknown. The louse is infected when feeding on blood of an infected individual, which it does five times a day. *R. prowazekii* multiplies in the gut of the louse and is released in feces. After a few days, it destroys the louse intestinal epithelium, thereby causing blood to spread from the gut. The patient is usually contaminated by infected feces (in which *R. prowazekii* survives for weeks), through aerosols, or by skin autoinoculation after scratching.

CLINICAL MANIFESTATIONS

Epidemic typhus begins abruptly with fever, headaches, and myalgias, which may lead to the crouched posture termed *sutama*, as observed in the largest recent outbreak in Burundi. Cough and neurologic signs (stupor, confusion, or coma) are common.[15] A rash, which is observed in 20 to 80% of patients, generally starts in the axilla and then spreads. The rash is usually macular but can be papular or purpuric in severe cases. In some cases, diarrhea and jaundice are reported. Splenomegaly is infrequently found. In severe cases, shock occurs. Leukopenia, thrombocytopenia, and anemia, as well as an increase in serum hepatic enzymes, may be noted.

Sylvatic typhus in the United States is caused by a *R. prowazekii* variant and is a milder disease. The most prominent clinical features are neurologic. Few cases have been described, and nearly all occurred in areas where the eastern flying squirrel is found, east of the Mississippi.

Brill-Zinsser disease, which is relapsed bacteremia typhus, is difficult to diagnose because a rash is rare and recent exposure to lice can be lacking. Interviewing the patient may reveal prior exposure to lice, associated or not with a history of epidemic typhus in previous years.

DIAGNOSIS

The diagnosis of typhus should be considered when grouped cases of high fever with confusion are observed in patients exposed to lice. The diagnosis of epidemic typhus should primarily be clinical because the fatality rate is high in untreated patients, whereas treatment is safe and efficient. Any outbreak of unexplained fever in unhygienic environments may suggest typhus, including outbreaks during civil wars, during social collapses, in jails, and in chronically poor countries, particularly in the cold season.

The diagnosis is mainly based on serology, with immunofluorescent assay being the reference method. However, cross-reaction with *R. typhi* is common (see earlier). When the investigation is performed under difficult field conditions, a drop of blood applied on filter paper and sent to a reference laboratory is valuable for serologic testing. Culture and PCR are helpful and can be performed with a skin biopsy sample or blood, but serology remains the preferred test. Lice are good diagnostic tools because they can be tested even when dry and can be sent in closed containers without specific temperature conditions.

The most common diagnostic error is to attribute the findings to typhoid (Chapter 284), which can have fatal consequences because the antimicrobials typically prescribed for that condition (β-lactams, cotrimoxazole, and quinolones) are ineffective treatment of typhus. In tropical countries, typhus is frequently confused with malaria (Chapter 316), viral hemorrhagic fever (Chapter 351), and dengue (Chapter 352). In people with lice, it can be confused with trench fever (Chapter 291) and relapsing fever (Chapter 297), but treatment for both can be prescribed.

TREATMENT

Treatment of typhus is extremely simple, cheap, and effective; 200 mg of doxycycline orally in two divided doses is life-saving. Comatose patients should be treated with intravenous doxycycline. In allergic patients, intravenous chloramphenicol is the only known alternative, prescribed at a dose of 2 g/day for 10 days. There is no current vaccination, and the fight against lice is the major prevention strategy. Because lice are fragile, changing and boiling clothes are efficient. When this is not possible, insecticides (primarily permethrin) or oral ivermectin should be used.

PROGNOSIS

The fatality rate of untreated epidemic typhus is 20 to 30%. Patients who recover from typhus may harbor the bacterium in a dormant form and suffer relapses under stressful conditions years later. In this relapsing form, named Brill-Zinsser disease, a bacteremia may allow the start of a new outbreak if lice bite the patient. Brill-Zinsser disease itself is mild, and the prognosis is good.

SCRUB TYPHUS (*ORIENTIA TSUTSUGAMUSHI*)

EPIDEMIOLOGY AND PATHOBIOLOGY

Scrub typhus is a neglected tropical disease transmitted by the bite of trombiculid mite (Chapter 98) larvae infected by *O. tsutsugamushi*. These mites, also named chiggers, are vertically infected by transovarial transmission. Although rare cases have been reported in Chile, sub-Saharan Africa, and United Arab Emirates, scrub typhus distribution is mostly limited to a triangle extending between northern Japan, eastern Australia, and eastern Russia, including the Far East, China, and the Indian subcontinent.[16] Altogether, 1 billion people may be exposed, and the number of annual cases is estimated to be 1 million. Travelers returning from endemic countries are also at risk.

Seasonality is determined by the emergence of mite larvae. Scrub typhus is one of the three most common causes of prolonged fever in rural Asia. In temperate zones, it occurs mainly in autumn and to a lesser extent in spring. *O. tsutsugamushi* exhibits a wide genetic heterogenicity that may allow the definition of several species, but a single species with many serotypes (the most frequent being Kato, Karp, Gilliam, and Kawasaki) is currently recognized.

CLINICAL MANIFESTATIONS

The disease occurs in patients exposed to rural or urban foci of scrub typhus after a delay of 10 or more days. The onset, which is usually sudden, includes fever, headache, and myalgias. Attentive examination may reveal an inoculation eschar at the site of the mite bite as well as tender draining lymph nodes. Most patients with scrub typhus present with relative bradycardia. Generalized lymphadenopathy and rash may be observed. The symptoms vary according to organ involvement. Neuromeningeal symptoms are relatively common.[17] Severe forms can present as septic shock.

Leukopenia, thrombocytopenia, and increased levels of hepatic enzymes can occur. Scrub typhus is not more severe in HIV-infected patients, and surprisingly, HIV-suppressive factors appear to be produced during infection.

DIAGNOSIS

Diagnosis may be difficult. Because the clinical features are frequently not specific, epidemiologic factors are critical. The bacterium can be detected by PCR of blood, CSF, pleural fluid, or biopsy specimens.[I8] The most reliable serologic techniques are immunofluorescence antibody assay and enzyme-linked immunosorbent assay tests using the three or four major serotypes. Point-of-care testing for scrub typhus still lacks standardized methodology and diagnostic accuracy.

TREATMENT

In severe forms, intravenous doxycycline (200 mg daily) is recommended for 7 days. Otherwise, the currently recommended regimen is doxycycline (100 mg orally twice a day, for 7 days).[A1] Single-day treatment with doxycycline is followed by relapses, and even repeated treatment for 2 days at a 7-day interval does not prevent all relapses. Cases resistant to doxycycline have been reported, and rifampin (600 mg orally daily) or chloramphenicol (2 g daily) may be used as alternative therapies.[A2] Quinolones should be avoided. Prophylaxis is based on the use of repellents.

PROGNOSIS

The mortality rate of untreated scrub typhus is 6% but can range from 0 to 30%, but the mortality is 1% or less with doxycycline treatment. Abortion commonly occurs in pregnant women. Relapses may occur in patients who initially respond to treatment.

RICKETTSIALPOX (*RICKETTSIA AKARI*)

EPIDEMIOLOGY AND PATHOBIOLOGY

Rickettsialpox was first described in New York City, where it is still prevalent. *Rickettsia akari*, the causal agent, is transmitted by the bite of the mouse mite (*Liponyssoides sanguineus*). Its prevalence is probably underestimated. Cases have also been reported in Arizona, Utah, and Ohio. High seroprevalence was reported among intravenous drug users in Baltimore. Cases have also been reported from Russia, Ukraine, Slovenia, South Africa, and Korea.

CLINICAL MANIFESTATIONS

Ten days after the mite bite, the onset of illness is marked by fever, headache, and myalgia. Careful examination reveals an inoculation eschar and draining lymphadenopathy that could be mistaken for cutaneous anthrax (Chapter 272). Two to 6 days later, a rash appears and comprises 5 to 40 macular and then papular and vesicular spots. This aspect led to the name of the disease. It is frequently mistaken for chickenpox (Chapter 346).

DIAGNOSIS

The diagnosis can be made by PCR of skin lesions or by immunofluorescent assay serologic testing. Specific antigens react with high titer, but cross reactions with other *Rickettsia* may be detected.

TREATMENT

Oral doxycycline (200 mg daily for 7 days) is highly effective in these patients. Prevention is based on the control of mice.

PROGNOSIS

The disease is usually mild and resolves even without treatment.

EHRLICHIOSES AND ANAPLASMOSES

EPIDEMIOLOGY AND PATHOBIOLOGY

Ehrlichioses can be acquired through tick bites, by ingestion of nematodes through contaminated water or animals (fish, snails), or as a consequence of filariasis. All *Ehrlichia* spp pathogenic for humans except *E. ewingii* can be cultured. The ehrlichiae have been reclassified into four genera, mainly on the basis of 16S ribosomal RNA–derived phylogenetic analysis. Two are the tick-associated genera *Ehrlichia* and *Anaplasma* (*A. phagocytophilum*). One is a helminth-associated genus, *Neorickettsia*, including *Neorickettsia sennetsu*. The fourth is *Wolbachia pipientis*, a bacterium associated with arthropods (insects, crustaceans, and acarids) and helminth worms (mainly filaria). These organisms elicit cross-reactive antibodies.

Ehrlichiae multiply exclusively in vacuoles of their eukaryotic cell host, where they form clusters known as morulae. The vacuoles are derived from phagosomes and help the organism escape bactericidal lysosomal fusion. In humans, ehrlichiae infect monocytes (*E. chaffeensis, E. canis, N. sennetsu*) or polymorphonuclear neutrophils (*A. phagocytophilum, E. ewingii*).

AMERICAN HUMAN MONOCYTIC EHRLICHIOSIS (*EHRLICHIA CHAFFEENSIS*)

EPIDEMIOLOGY

Human monocytic ehrlichiosis is caused by *E. chaffeensis*. This organism has been isolated or identified by PCR mainly in the United States, particularly in the southeastern, south central, and mid-Atlantic states and in California (Table 302-3). In the United States, *A. americanum* (Lone Star tick) is the vector (Chapter 98), and the white-tailed deer is the main mammalian reservoir. Immature ticks are infected by blood while feeding on persistently bacteremic mammals. *E. chaffeensis* is transmitted transstadially in the tick and infects its next host (deer or human) during its next blood meal.

The epidemiology of the disease reflects the tick's habitat and activity, with most cases being contracted in the Southern United States, in rural areas, and from April to September. In 2019, 2000 cases were reported to the Centers for Disease Control and Prevention (CDC). The severity is age-dependent, which may explain the lower incidence reported in children. Males are more often affected than females, with a sex ratio of 4:1.

CLINICAL MANIFESTATIONS

The incubation is about 7 to 10 days after an identified tick exposure in 80% of cases. Patients have fever, headache, malaise, nausea, and anorexia. Untreated patients worsen and may require intensive care. Digestive tract involvement consisting of nausea, vomiting, diarrhea, and abdominal pain is common. Central nervous system infection may be polymorphic, ranging from confusion to coma. A rash is observed in one third of cases and lymphadenopathy in one fourth. In severe forms, sepsis syndrome and multiple organ dysfunction may occur.

The white blood cell count typically shows both lymphopenia and neutropenia. Thrombocytopenia is also frequent, and anemia may appear later. In severe forms, coagulopathy may be observed. Increases in aminotransferase levels indicate liver involvement, and renal dysfunction can occur. CSF examination in patients with neurologic symptoms reveals pleocytosis (with monocytes or neutrophils) and increased protein levels.

DIAGNOSIS

The diagnosis of human monocytic ehrlichiosis should be considered in patients with a history of tick exposure and unexplained fever. The disease resembles Rocky Mountain spotted fever, but rash is less frequent. Later in the disease,

TABLE 302-3 EHRLICHIOSES AND ANAPLASMOSES

DISEASE	AGENT	VECTOR	GEOGRAPHIC REPARTITION
American monocytic ehrlichiosis	*Ehrlichia chaffeensis*	*Amblyomma americanum*	South central, southeastern, mid-Atlantic coastal states
Human granulocytic ehrlichiosis	*Anaplasma phagocytophilum*	*Ixodes ricinus* *Ixodes scapularis*	Europe, China Northeast, upper Midwest, northern California
Japanese monocytic ehrlichiosis	*Neorickettsia sennetsu*	Helminth of the gray mullet?	Japan
Unnamed	*Ehrlichia canis*	*Rhipicephalus sanguineus*	Venezuela
	Ehrlichia ewingii	*Amblyomma americanum*	South central, southeastern, mid-Atlantic coastal states
	Ehrlichia muris–like	*Ixodes scapularis*	Indiana, Michigan, Minnesota, North Dakota, Wisconsin
	Candidatus Neoehrlichia mikurensis	*Ixodes ricinus*	Central and Eastern Europe, northeastern China

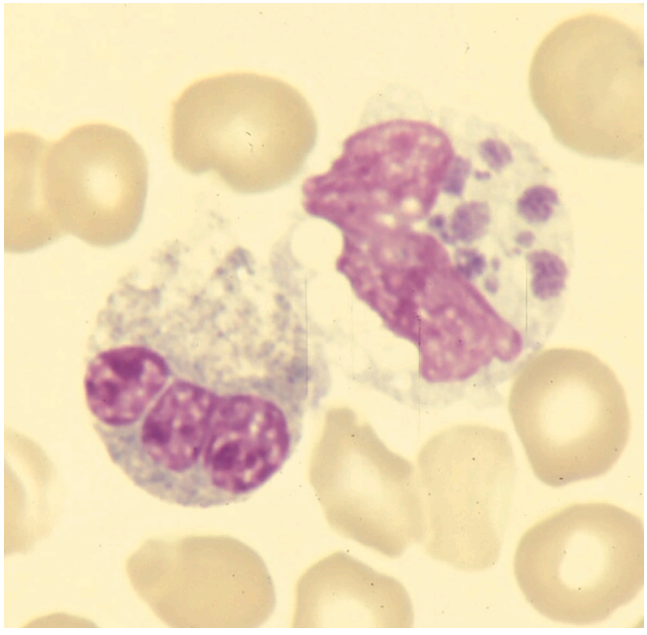

FIGURE 302-5. Blood smear in *Ehrlichia*. Note *Ehrlichia chaffeensis* morulae in a monocyte. (Courtesy Christopher D. Paddock, Centers for Disease Control and Prevention, Atlanta, GA, USA.)

human monocytic ehrlichiosis can be misdiagnosed as any other cause of severe sepsis (Chapter 94).

Leukopenia associated with thrombocytopenia and an increase in liver enzyme levels may suggest the diagnosis. Careful examination of blood and CSF smears may help identify typical morulae (Fig. 302-5).

The diagnosis can be made by PCR of blood or CSF.[19] Alternatively, seroconversion or a four-fold or greater increase in antibody titer by immunofluorescent assay is also diagnostic. Cross-reactive antibodies are common among *Ehrlichia* species and with *A. phagocytophilum*. Western blotting may be valuable to distinguish among these bacteria.

TREATMENT

Suspected cases should be treated without delay. Doxycycline (100 mg twice daily for adults) is the drug of choice for ehrlichiosis. The optimal duration of therapy has not been established, but current regimens recommend continuation of treatment for at least 3 days after the fever subsides and until evidence of clinical improvement, for a minimum total course of 5 to 7 days. Because tetracyclines are contraindicated in pregnancy, rifampin (10 mg/kg/day for 10 days) has been used successfully in a limited number of pregnant women with documented human monocytic ehrlichiosis.

PROGNOSIS

The prognosis depends on early antimicrobial treatment, but the fatality rate is still about 2.5% even with treatment.[20] In persons coinfected with HIV, it may be most severe; in one series, 6 of 13 patients died.

HUMAN GRANULOCYTIC EHRLICHIOSIS (*ANAPLASMA PHAGOCYTOPHILUM*)

EPIDEMIOLOGY AND PATHOBIOLOGY

A. phagocytophilum infection is distributed in America, Asia, and Europe (Fig. 302-6). It is transmitted by *Ixodes* ticks (*I. scapularis* [eastern North America], *I. pacificus* [western North America], *I. ricinus* [Europe], and *I. persulcatus* [Asia]), which are the vectors of Lyme disease (Chapter 296), and its epidemiology is similar.[21] Coinfection with the two diseases may occur. The temporal distribution of the disease parallels that of nymph tick activity, with two peaks in spring and autumn.

In 2017, a peak of 5762 cases was reported to the CDC. Males are more frequently infected than females, with a sex ratio of 3:1.

Ticks are born free of *A. phagocytophilum* and are infected while feeding on bacteremic small mammals. Deer play a major role as hosts of adult ticks and reservoirs.

CLINICAL MANIFESTATIONS

The incubation time is usually between 7 and 10 days, and 80% of patients report a history of tick exposure. Many infections may be asymptomatic or too mild to require a diagnostic procedure. The onset of disease is frequently abrupt, with fever, headache, malaise, and myalgias that may be particularly severe. A rash is found in less than 10% of cases. Visceral involvement can include digestive symptoms such as nausea, vomiting, and diarrhea. Neurologic symptoms may include confusion, meningitis, and meningoencephalitis.

Laboratory findings consist of the association of thrombocytopenia and leukopenia. Serum aminotransferase levels are frequently elevated.

DIAGNOSIS

PCR of blood can easily confirm the diagnosis. An alternative is serologic testing with an immunofluorescent assay, which is comparable to that in human monocytic ehrlichiosis (see earlier). The diagnosis can also be made by careful examination of blood smears for morulae within neutrophils. Culture from blood is also possible.

TREATMENT

Treatment is similar to that of human monocytic ehrlichiosis—doxycycline 100 mg twice daily for at least 5 to 7 days and at least 3 days after fever resolves and symptoms improve.

PROGNOSIS

The prognosis of the disease is favorable in most cases, even without specific therapy, but the disease may progress to septic shock in some patients.[22] Patients with underlying diseases are more at risk for death. However, the case fatality rate is less than 1%. Most deaths are the consequence of *Anaplasma*-induced immunosuppression, and patients may develop opportunistic infections such as invasive aspergillosis, candidiasis, cryptococcosis, and herpes esophagitis.

OTHER *EHRLICHIA*

Canine granulocytic ehrlichiosis is caused by *E. ewingii*. The vector of *E. ewingii* is *Amblyomma americanum*, which also transmits *E. chaffeensis*. To date, more than 260 cases of *E. ewingii* infection have been reported to the CDC. The disease has been prevalent in immunocompromised hosts coinfected with HIV or receiving immunosuppressive drugs. Patients who report tick exposure exhibit fever, thrombocytopenia, leukopenia, and various symptoms, including meningitis. Morulae may be seen in neutrophils on blood smears. The diagnosis should be considered when ehrlichiosis is suspected in immunocompromised patients exposed to *A. americanum* ticks.

Canine monocytic ehrlichiosis is caused by *E. canis* and transmitted by the dog tick *R. sanguineus*. This tick is found worldwide and is prevalent in temperate and hot areas. Recently, cases have been reported in patients in Venezuela and Costa Rica. Signs and symptoms are similar to those caused by *E. ewingii*.

More than 60 cases of ehrlichiosis have been caused by an *Ehrlichia* that is closely related to *E. muris*. The bacterium has also been cultured from *Ixodes scapularis* ticks in Wisconsin and Minnesota. Patients have fever, headache, myalgias, lymphopenia, thrombocytopenia, and elevated aminotransferase levels. *Candidatus* N. mikurensis, transmitted by *Ixodes* ticks, has been reported in febrile immunocompromised patients in Europe and China.

DIAGNOSIS, TREATMENT, AND PROGNOSIS

For these *Ehrlichia*, PCR of blood can be diagnostic. Patients respond dramatically to doxycycline as for *E. chaffeensis*. The prognosis in treated patients is good.

WOLBACHIA SPECIES

Wolbachia bacteria are endosymbionts of arthropods and nematodes. These bacteria manipulate the fertility of their host. Eradication of *Wolbachia* in filariae may lead to infertility and stop the microfilariae from spreading. This effect was demonstrated by field treatment with doxycycline in patients with onchocerciasis (Chapter 327). The patients improved when treated with this drug, which is effective on *Wolbachia* and subsequently on the worm's fertility but not on the worm itself. The adverse reactions observed after treatment of lymphatic filariasis (Chapter 327) may be caused by the release of *Wolbachia* from destroyed worms. Some experts suggested that eradicating *Wolbachia*

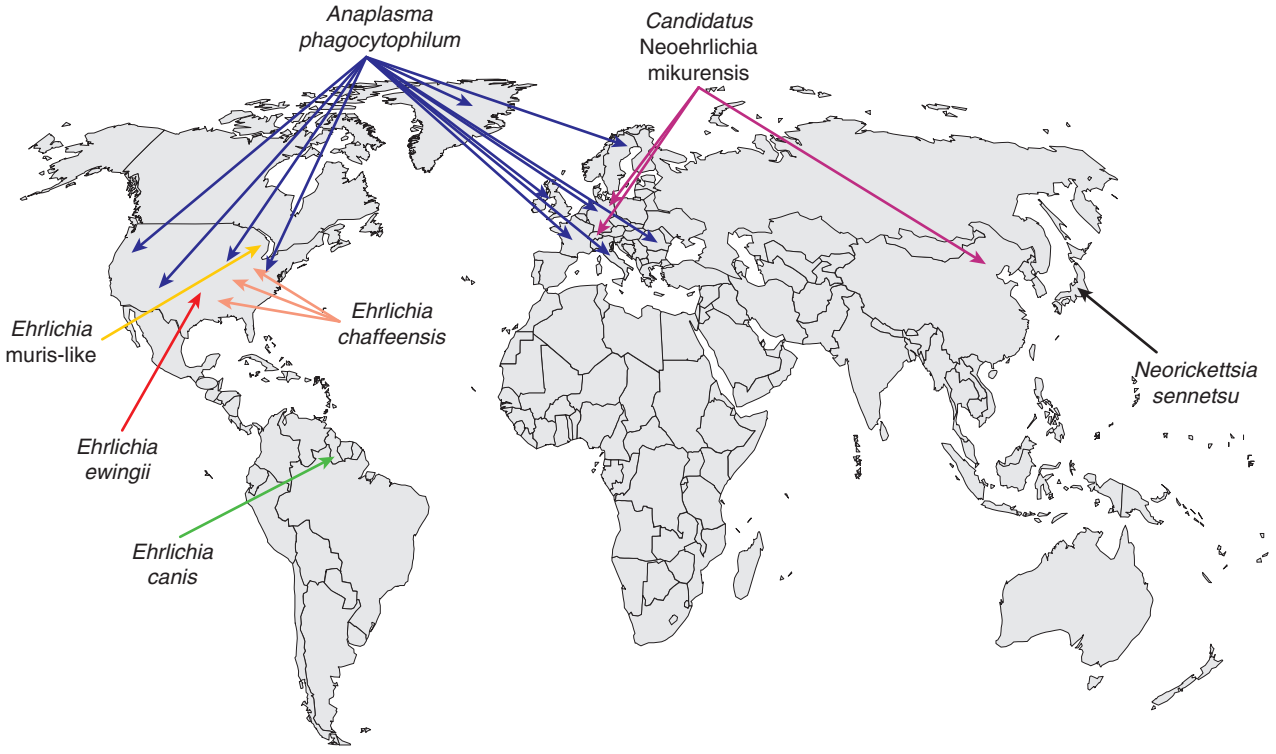

FIGURE 302-6. **Geographic distribution of ehrlichioses.**

using oral doxycycline (200 mg daily) before the anthelmintic prescription would avoid these reactions. *Loa loa* (Chapter 327) do not harbor *Wolbachia*, and the genome of *Wolbachia* integrated in the *Brugia malayi* genome makes it inaccessible to therapy.

Q FEVER

EPIDEMIOLOGY

Q fever is a worldwide zoonosis caused by *Coxiella burnetii*. Human infection varies in its severity, clinical expression, and natural course (i.e., acute or chronic). It is considered by the CDC to be a potential agent of bioterrorism.

C. burnetii infects a wide range of domestic and wild animals, including mammals, birds, and ticks. Ungulates are the most common source of the disease. Mammals are infected through aerosols and may shed *Coxiella* in feces, urine, milk, and birth products. Ruminants, in particular sheep and goats, are the major sources of human infection. Infection may occasionally be acquired following contact with pets.

Humans are usually infected by aerosols or, less frequently, by exposure to milk products. Rare cases of interhuman infections through sexual intercourse, during delivery, or by blood transfusion have been reported.

Coxiella can survive in the environment and can be spread far by the wind. The disease may cause outbreaks following exposure to infected sheep and goats. A large outbreak (>4000 cases) was reported in the Netherlands from 2007 to 2010. The disease is partly seasonal and related to lambing time. Males have more severe disease but are not more often exposed to Q fever, and middle-aged people are more frequently affected and hospitalized.[23] The number of reported cases recently increased dramatically in Europe and Asia. Many American soldiers were infected in Iraq.

PATHOBIOLOGY

C. burnetii is a gram-negative bacterium that naturally infects its host's monocytes and endothelial cells. In macrophages, the bacterium multiplies in an acidic vacuole, the phagolysosome. Strains are heterogeneous genetically and antigenically, and they cause acute infections of variable severity. In vitro, *C. burnetii* generates a deleted mutant also named phase II. This mutant exhibits diagnostic antigens that are useful because they are more reactive during acute infection.

C. burnetii may persist in the human body after acute infection. In immunocompromised hosts and patients with infected cardiac valves or arterial lesions, *C. burnetii* is able to multiply despite high levels of antibodies and to cause chronic infections. Control of the disease in acute Q fever is associated with the formation of a granuloma.

CLINICAL MANIFESTATIONS

After contamination by *C. burnetii*, 60% of patients seroconvert without apparent disease, 38% experience a self-limited disease, and only 2% require diagnostic evaluation.[24] Months to years after the primary infection, a chronic infection develops in 0.2 to 0.5% of patients, associated with an immunocompromised state, a cardiac valve lesion, or a vascular prosthesis or aneurysm.[25]

Patients with acute infection may have a variety of symptoms and signs (Table 302-4). Isolated prolonged fever was observed in 15% of patients.

TABLE 302-4 SITUATIONS THAT SHOULD PROMPT SEROLOGIC TESTING FOR Q FEVER

ACUTE Q FEVER (PHASE II ANTIGEN AND IgG ≥200 AND IgM ≥50)
Fever in a patient in contact with ungulates (hoofed mammals)
Unexplained prolonged fever (>7 days)
Granulomatous hepatitis
Fever and thrombocytopenia
Meningoencephalitis
Myocarditis
Erythema nodosum
Fever during pregnancy
Fever in a patient in contact with a parturient pet
Unexplained atypical pneumonia
Fever and an increase in transaminases (2-5 times the normal level)
Aseptic meningitis
Guillain-Barré syndrome
Pericarditis
Spontaneous abortion
CHRONIC Q FEVER (PHASE I ANTIGEN AND IgG ≥800 AND IgA ≥100)
Blood culture–negative endocarditis
Patient with a valvulopathy and unexplained:
Fever
Weight loss
Fatigue
Increased erythrocyte sedimentation rate
Increased transaminases
Thrombocytopenia
Patient with unusually rapid degradation of a prosthetic valve
Fever in a patient with a vascular aneurysm or prosthesis
Aseptic osteomyelitis
Chronic pericarditis
Multiple spontaneous abortions

Ig = immunoglobulin.

Pneumonia is found in 35 to 40% and is the only symptom in 15 to 20%. Some cases may be associated with respiratory distress. Hepatitis is found in about 60% of patients and is the sole manifestation in about 40%. The association of fever and a moderate increase in aminotransferase levels is an important clue. Other rare manifestations, which occur in only 1 to 2% of cases, include a rash, neurologic manifestations (e.g., meningitis, encephalitis, meningoencephalitis, or peripheral neuropathy), cardiovascular manifestations (e.g., pericarditis, or, more rarely, myocarditis or acute endocarditis), and prosthetic joint infection.

Patients with chronic Q fever endocarditis (Chapter 61) often suffer from low-grade fever, progressive degradation of valve function, and progressive heart failure. Fever is intermittent, and vegetations are frequently absent on echocardiography. Endocarditis is therefore not frequently considered in the initial differential diagnosis. If it is not diagnosed, the disease progressively worsens, and it can be complicated by emboli (mainly cerebral), renal insufficiency, splenomegaly, and hepatomegaly. Digital clubbing may also be seen. Chronic osteomyelitis, hepatitis, and infection of an aneurysm and vascular prosthesis have been reported.[26]

Thrombocytopenia is frequent, as are increases in hepatic enzymes; leukopenia may be observed. A lupus anticoagulant associated with antiphospholipid antibodies may be detectable (Chapter 160), as may anti–smooth muscle antibodies. With endocarditis, antinuclear antibodies, microhematuria, and a positive rheumatoid factor are frequent.

DIAGNOSIS

The main clue to the diagnosis in a patient with a valvulopathy and exposure to ungulates is unexplained sickness (fatigue, weight loss, fever), a biologic abnormality (leukopenia, increased erythrocyte sedimentation rate, thrombocytopenia, increase in hepatic enzymes), or rapid degradation of a prosthetic valve. The diagnosis is mainly based on serology (see Table 302-4). Direct detection by PCR, culture, or immunochemistry in valve, liver, or blood samples is also useful, but serologic evaluation by immunofluorescent assay is the reference method. Two antigens (phase I and phase II) can be tested. Acute Q fever is diagnosed when seroconversion or a four-fold increase is obtained with phase II antigen. A single serum test exhibiting IgG antibodies of 200 or greater and IgM of 50 or greater against phase II is also diagnostic. During chronic Q fever, antibodies are at higher titer and directed against both phase I and phase II. IgG against phase I at a titer of 800 or 1600 is diagnostic of chronic infection, as is IgA at 100 or greater. Serology also is useful for following patients with acute Q fever and with treated chronic Q fever.

Routine echocardiography may be warranted to diagnose or exclude endocarditis in all patients with acute Q fever, in whom the overall prevalence of endocarditis is about 3%.[27] In patients with vascular infection or prosthetic valve endocarditis, fluorodeoxyglucose (FDG)–positron emission tomography (PET)/computed tomography (CT) has proved useful. In patients with hepatic abnormalities, liver biopsy, when performed, exhibits granulomas that may be typified by a doughnut shape, with a lipid vacuole that is surrounded by a fibrinoid ring.

TREATMENT

For acute Q fever, oral doxycycline (200 mg daily) is the most efficient antimicrobial, and it should be prescribed for 2 weeks. Some patients with hepatitis do not respond well because of an excessive immune response; these patients rapidly improve with a short course of glucocorticoids (e.g., prednisolone 10 mg daily for 3 days). In pregnant women, doxycycline is contraindicated, but oral cotrimoxazole (320 mg of trimethoprim and 1600 mg of sulfamethoxazole daily) during the entire pregnancy may decrease the chance of an unfavorable outcome.

For endocarditis and for chronic Q fever, which occurs in 1 to 5% of patients,[28] the recommended treatment is a combination of doxycycline (200 mg daily) and hydroxychloroquine (600 mg/day, then adjusted to reach a 1-mg/mL plasma concentration). This regimen is prescribed for 18 to 36 months based on serologic results. The major adverse effect of this treatment is photosensitivity; sun exposure should be avoided. A more rapid favorable outcome can be obtained with doxycycline serum levels higher than 5 μg/mL.

An alternative treatment is a combination of doxycycline and ofloxacin for 3 years or more. Some strains may be resistant to doxycycline (200 mg daily), and macrolides may be an alternative.

PREVENTION

Prevention is based on veterinary control in animals. A human vaccine is currently available in Australia.

PROGNOSIS

Prognosis is usually favorable even without treatment. In pregnant women, symptomatic or not, Q fever may compromise the pregnancy. When infected during the first trimester, the patient usually aborts spontaneously. When the patient is infected later, the disease can result in fetal death or prematurity, although in many the outcome may be normal. Chronic uterine infection may develop in 50% of the patients infected during pregnancy, and these women may later experience multiple spontaneous abortions. Thirty to 50% of patients with heart valve or vascular lesions may experience chronic endocarditis or vascular infection within 2 years. This development is not prevented by initial treatment. The mortality of Q fever endocarditis is about 10%.

303 ZOONOSES

MEGAN E. RELLER AND J. STEPHEN DUMLER

DEFINITION

Zoonoses, derived from the Greek words *zōio* (animal) and *nósos* (disease), are infectious diseases transmitted from animals, both wild and domestic, to humans or from humans to animals. Among emerging or reemerging infectious diseases, 60 to 75% are zoonoses. Most recently, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapters 335, 336, and 337) has shown the devastating effects of zoonotic transmission[1–3] followed by travel-related human spread.

EPIDEMIOLOGY AND PATHOBIOLOGY

Zoonotic pathogens or their toxins can be transmitted by several different routes: direct contact with animals or their products (e.g., tissue, urine, or excreta); animal bites and scratches; arthropod vectors; and consumption of contaminated food or water. Zika virus (Chapter 352), *Borrelia burgdorferi* (Chapter 297), *Babesia microti* (Chapter 324), and *Plasmodium knowlesi* (Chapter 316) are well-recognized vector-transmitted zoonotic pathogens.[4] However, many arthropod vector–borne pathogens, such as *Plasmodium falciparum* (Chapter 316) or *Bartonella quintana* (Chapter 291), are not zoonotic because they are transmitted from human to human through the vector but lack an animal reservoir. Similarly, many infections acquired from the environment also are not zoonoses; examples include melioidosis (*Burkholderia pseudomallei*; Chapter 282) and histoplasmosis (*Histoplasma capsulatum*; Chapter 308). Understanding the epidemiology and transmission of zoonotic versus nonzoonotic infections is critical for implementing control measures at local, regional, and international levels.

Zoonotic spillover occurs when barriers that prevent a zoonotic agent from gaining access to and infecting a human are breached or fail. Such issues include factors related to the interaction between the reservoir host and the pathogen, including where the reservoir host lives; the prevalence of the pathogen within the host; the likelihood of its release from the infected reservoir host; the ability of the pathogen to survive and disseminate after release from the host; and human characteristics that affect the ability of the pathogen to enter and propagate within humans, such as structural barriers, immunity to infection,

Pneumonia is found in 35 to 40% and is the only symptom in 15 to 20%. Some cases may be associated with respiratory distress. Hepatitis is found in about 60% of patients and is the sole manifestation in about 40%. The association of fever and a moderate increase in aminotransferase levels is an important clue. Other rare manifestations, which occur in only 1 to 2% of cases, include a rash, neurologic manifestations (e.g., meningitis, encephalitis, meningoencephalitis, or peripheral neuropathy), cardiovascular manifestations (e.g., pericarditis, or, more rarely, myocarditis or acute endocarditis), and prosthetic joint infection.

Patients with chronic Q fever endocarditis (Chapter 61) often suffer from low-grade fever, progressive degradation of valve function, and progressive heart failure. Fever is intermittent, and vegetations are frequently absent on echocardiography. Endocarditis is therefore not frequently considered in the initial differential diagnosis. If it is not diagnosed, the disease progressively worsens, and it can be complicated by emboli (mainly cerebral), renal insufficiency, splenomegaly, and hepatomegaly. Digital clubbing may also be seen. Chronic osteomyelitis, hepatitis, and infection of an aneurysm and vascular prosthesis have been reported.[26]

Thrombocytopenia is frequent, as are increases in hepatic enzymes; leukopenia may be observed. A lupus anticoagulant associated with antiphospholipid antibodies may be detectable (Chapter 160), as may anti–smooth muscle antibodies. With endocarditis, antinuclear antibodies, microhematuria, and a positive rheumatoid factor are frequent.

DIAGNOSIS

The main clue to the diagnosis in a patient with a valvulopathy and exposure to ungulates is unexplained sickness (fatigue, weight loss, fever), a biologic abnormality (leukopenia, increased erythrocyte sedimentation rate, thrombocytopenia, increase in hepatic enzymes), or rapid degradation of a prosthetic valve. The diagnosis is mainly based on serology (see Table 302-4). Direct detection by PCR, culture, or immunochemistry in valve, liver, or blood samples is also useful, but serologic evaluation by immunofluorescent assay is the reference method. Two antigens (phase I and phase II) can be tested. Acute Q fever is diagnosed when seroconversion or a four-fold increase is obtained with phase II antigen. A single serum test exhibiting IgG antibodies of 200 or greater and IgM of 50 or greater against phase II is also diagnostic. During chronic Q fever, antibodies are at higher titer and directed against both phase I and phase II. IgG against phase I at a titer of 800 or 1600 is diagnostic of chronic infection, as is IgA at 100 or greater. Serology also is useful for following patients with acute Q fever and with treated chronic Q fever.

Routine echocardiography may be warranted to diagnose or exclude endocarditis in all patients with acute Q fever, in whom the overall prevalence of endocarditis is about 3%.[27] In patients with vascular infection or prosthetic valve endocarditis, fluorodeoxyglucose (FDG)–positron emission tomography (PET)/computed tomography (CT) has proved useful. In patients with hepatic abnormalities, liver biopsy, when performed, exhibits granulomas that may be typified by a doughnut shape, with a lipid vacuole that is surrounded by a fibrinoid ring.

TREATMENT

For acute Q fever, oral doxycycline (200 mg daily) is the most efficient antimicrobial, and it should be prescribed for 2 weeks. Some patients with hepatitis do not respond well because of an excessive immune response; these patients rapidly improve with a short course of glucocorticoids (e.g., prednisolone 10 mg daily for 3 days). In pregnant women, doxycycline is contraindicated, but oral cotrimoxazole (320 mg of trimethoprim and 1600 mg of sulfamethoxazole daily) during the entire pregnancy may decrease the chance of an unfavorable outcome.

For endocarditis and for chronic Q fever, which occurs in 1 to 5% of patients,[28] the recommended treatment is a combination of doxycycline (200 mg daily) and hydroxychloroquine (600 mg/day, then adjusted to reach a 1-mg/mL plasma concentration). This regimen is prescribed for 18 to 36 months based on serologic results. The major adverse effect of this treatment is photosensitivity; sun exposure should be avoided. A more rapid favorable outcome can be obtained with doxycycline serum levels higher than 5 μg/mL.

An alternative treatment is a combination of doxycycline and ofloxacin for 3 years or more. Some strains may be resistant to doxycycline (200 mg daily), and macrolides may be an alternative.

PREVENTION

Prevention is based on veterinary control in animals. A human vaccine is currently available in Australia.

PROGNOSIS

Prognosis is usually favorable even without treatment. In pregnant women, symptomatic or not, Q fever may compromise the pregnancy. When infected during the first trimester, the patient usually aborts spontaneously. When the patient is infected later, the disease can result in fetal death or prematurity, although in many the outcome may be normal. Chronic uterine infection may develop in 50% of the patients infected during pregnancy, and these women may later experience multiple spontaneous abortions. Thirty to 50% of patients with heart valve or vascular lesions may experience chronic endocarditis or vascular infection within 2 years. This development is not prevented by initial treatment. The mortality of Q fever endocarditis is about 10%.

303 ZOONOSES

MEGAN E. RELLER AND J. STEPHEN DUMLER

DEFINITION

Zoonoses, derived from the Greek words *zōio* (animal) and *nósos* (disease), are infectious diseases transmitted from animals, both wild and domestic, to humans or from humans to animals. Among emerging or reemerging infectious diseases, 60 to 75% are zoonoses. Most recently, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapters 335, 336, and 337) has shown the devastating effects of zoonotic transmission[1–3] followed by travel-related human spread.

EPIDEMIOLOGY AND PATHOBIOLOGY

Zoonotic pathogens or their toxins can be transmitted by several different routes: direct contact with animals or their products (e.g., tissue, urine, or excreta); animal bites and scratches; arthropod vectors; and consumption of contaminated food or water. Zika virus (Chapter 352), *Borrelia burgdorferi* (Chapter 297), *Babesia microti* (Chapter 324), and *Plasmodium knowlesi* (Chapter 316) are well-recognized vector-transmitted zoonotic pathogens.[4] However, many arthropod vector–borne pathogens, such as *Plasmodium falciparum* (Chapter 316) or *Bartonella quintana* (Chapter 291), are not zoonotic because they are transmitted from human to human through the vector but lack an animal reservoir. Similarly, many infections acquired from the environment also are not zoonoses; examples include melioidosis (*Burkholderia pseudomallei*; Chapter 282) and histoplasmosis (*Histoplasma capsulatum*; Chapter 308). Understanding the epidemiology and transmission of zoonotic versus nonzoonotic infections is critical for implementing control measures at local, regional, and international levels.

Zoonotic spillover occurs when barriers that prevent a zoonotic agent from gaining access to and infecting a human are breached or fail. Such issues include factors related to the interaction between the reservoir host and the pathogen, including where the reservoir host lives; the prevalence of the pathogen within the host; the likelihood of its release from the infected reservoir host; the ability of the pathogen to survive and disseminate after release from the host; and human characteristics that affect the ability of the pathogen to enter and propagate within humans, such as structural barriers, immunity to infection,

ABSTRACT

Zoonoses are infections and/or diseases acquired by humans from animals. They are distinct from anthroponoses that only involve humans, even if infected through an arthropod vector. Zoonoses make up a significant proportion of all emerging infections and are caused by a complete range of pathogens, including prions, viruses, bacteria, fungi, protozoa, and helminths. The emergence of zoonoses is in part determined by the concept of zoonotic "spillover," whereby barriers that prevent access of zoonotic agents to humans are breached.

Specific risks for emergence of zoonoses include origins in tropical forest regions; increases in mammal biodiversity; and changes in land use due to agricultural practices, residential encroachment, and urban development. Zoonoses can be acquired by direct animal contact, animal bites or scratches, bites or mechanical transmission from arthropod vectors, and consumption of contaminated food or water. The clinical manifestations, diagnostic methods, and treatments are specific for individual infectious agents and disease, but many can be prevented by appropriate use of vaccines, protective clothing, and other prophylactic measures.

zoonotic spillover

and genetic predisposition to infection. Zoonotic infections, not surprisingly, are difficult to predict because distinct barriers are not equally shared for each pathogen/reservoir combination owing to the great genomic diversity of animals, humans, and microbes.[5]

In the United States, about 60% of people own a pet. Dogs and cats are most frequent. However, other pets include fish, birds, reptiles, hamsters, guinea pigs, rabbits, and horses. Moreover, exotic animals, including large cats, primates, and bears, are legal with or without a permit in many U.S. states. Wildlife-related recreation exposes more than 90 million U.S. residents to increased risk for zoonoses, and 72 million observe, feed, or photograph birds and other wildlife.

Climate change (Chapter 16) can both increase the likelihood of spillovers (the complicated process by which pathogens defy natural barriers and infect new animal species) and affect chains of transmission.[6] Climate change is expected to increase the risk for zoonoses over the next 50 years because of extreme temperatures that cause increased rainfall and violent storms, rising sea level and floods that could augment zoonotic diarrheal disease, loss of biodiversity, collapse of ecosystems, an increase in pests, and the spread and increase in both neopteran (biting insect) and acarid (tick and mite) vectors of zoonotic pathogens.

Most emerging zoonoses are acquired from contact with wildlife.[7] Key factors that predict emergence of zoonoses are origin in tropical forest regions, increases in mammal biodiversity, changes in anthropogenic land use related to agricultural practices, and illegal wildlife trade[8] (Fig. 303-1). Residential and other land development directly related to human activity is by far the strongest predictor of risk.

Zoonoses are transmitted through one or more of several mechanisms: direct contact with animals or infected materials and/or related inhalation; animal bites and scratches; bites or mechanical transmission by arthropod vectors; and consumption of contaminated foods (Table 303-1). Direct contact with animals is a well-documented mechanism for acquiring viral, bacterial, protozoan, and fungal zoonotic pathogens. The risk is particularly high for individuals whose occupations or recreations involve contact with animals. For example, in a study of veterinarians in Oregon, contact-related ringworm was the most common zoonosis, and rabies the most dangerous; cats were the most likely source of contact-related zoonoses. Significant risks also exist for farmers, abattoir workers, and animal handlers. Leptospirosis (Chapter 298),[9] which likely is one of the most neglected of all zoonoses worldwide with an estimated 1 million cases and nearly 60,000 deaths annually, is commonly acquired through direct contact with contaminated rodent urine; however, many wild and domestic animals can become colonized and excrete the spirochete in their urine. *Coxiella burnetii* (Chapter 302) is distributed worldwide and acquired by inhalation of dust contaminated with excretions, such as milk, urine, and feces, and/or birth products, from infected animals.[10]

In addition to direct tissue injury, animal scratches and bites are a common cause of zoonotic infections. In the United States alone, an estimated 4.5 million dog bites occur annually and 900,000 result in infection; therefore, approximately 1 in every 72 people is affected. Examples of pathogens include *Capnocytophaga canimorsus* from dog bites, as well as *Pasteurella multocida* (Chapter 288) and *Bartonella henselae,* the etiologic agent of cat-scratch disease, from cat bites. In some regions of the world, endemic rabies (Chapter 383) is rampant.

Perhaps the best known zoonoses are transmitted through arthropod bites, such as mosquitoes, flies, or ticks and mites. Vector-borne zoonotic viral infections include West Nile virus (Chapter 352), Eastern equine encephalitis virus (Chapter 352), Nipah virus (Chapter 383), and Hendra virus (Chapter 331). *P. knowlesi* (Chapter 316), *Babesia microti* (Chapter 324), *Leishmania* spp (Chapter 319), and *Trypanosoma* spp (Chapters 317 and 318) are examples of vector-borne zoonotic protozoal infections. *Leishmania*, with 700,000 to 1 million new cases per year, is associated with epidemics across southern Asia, northern Africa, and South America.[11] *Trypanosoma brucei rhodesiense* and *T. brucei gambiense,* agents of African trypanosomiasis and human sleeping sickness (Chapter 317), are transmitted by biting tsetse flies in Africa; cases have been declining in recent years as a result of control efforts, with fewer than 1000 new cases reported in 2019 despite an estimated 65 million people at risk.[12]

Ticks and mites are the most important vectors of zoonotic disease in the developed world. In the United States from 2012 to 2016, 217,000 of 242,000 (90%) reported cases of vector-borne zoonosis were attributed to tick-borne infections, especially *B. burgdorferi* (Chapter 297; Fig. 303-2); recent studies provide evidence that the actual number of *B. burgdorferi* infections is more than 10 times that reported. Worldwide, ticks, lice, and mites are also significant, but underrecognized, causes of vector-borne bacterial zoonoses. Examples of neglected vector-borne bacterial zoonotic disease include tick- and louse-borne relapsing fever borreliosis (Chapter 297); spotted fever group rickettsioses (Chapter 302), transmitted principally by hard body (ixodid) ticks; and typhus group rickettsioses (Chapter 302), transmitted by fleas and lice. Scrub typhus (Chapter 302), caused by the rickettsia *Orientia tsutsugamushi* and transmitted by the larval stage (chigger) of a trombiculid mite, occurs across much of Asia and Oceania and is now emerging in Africa and South America; it is estimated to cause as many as 1,000,000 infections each year globally.[13]

Many important zoonotic infections are acquired through consumption of contaminated foods or water. The list of potential pathogenic agents is vast and includes viruses (such as hepatitis A and E virus; Chapter 134); prions (such as bovine spongiform encephalopathy; Chapter 371); bacteria (e.g., *Salmonella* [Chapter 284], *Campylobacter* [Chapter 279], *Listeria* [Chapter 272]; and *Brucella* [Chapter 286]); protozoa (such as *Cyclospora* [Chapter 324], *Cryptosporidium* [Chapter 321], *Toxoplasma* [Chapter 320],[14] and *Giardia* [Chapter 322]); and helminths (such as *Taenia* [Chapter 325], *Trichinella* [Chapter 327], *Opisthorchis* [Chapter 326], and *Clonorchis* [Chapter 326]).

CLINICAL MANIFESTATIONS

The clinical manifestations of zoonoses are as variable as those for nonzoonotic infections. Symptoms and signs may be referent to the skin, the gastrointestinal tract, the respiratory tract, the central nervous system, the musculoskeletal system, or major organs such as liver, kidneys, and heart; zoonotic infections can also present as undifferentiated fever,[15] sepsis, or toxic shock–like syndromes. For the clinical manifestations with specific zoonotic agents or syndromes, the individual chapters that address each should be consulted. Although most zoonoses are acquired locally, early identification requires taking a comprehensive history, including possible animal exposures and domestic and international travel.

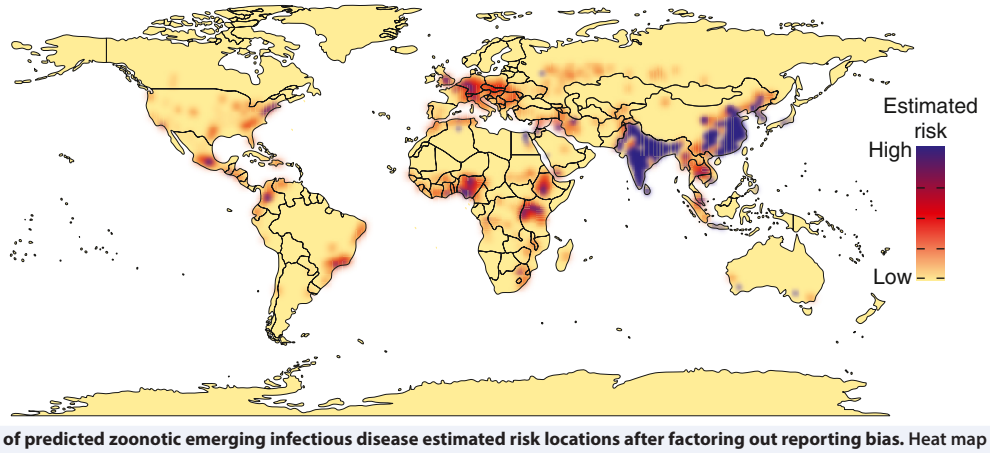

FIGURE 303-1. Heat map of predicted zoonotic emerging infectious disease estimated risk locations after factoring out reporting bias. Heat map estimated risk scale on right: highest risk is *blue*; lowest risk is *yellow*. (Adapted from Allen T, Murray KA, Zambrana-Torrelio C. Global hotspots and correlates of emerging zoonotic diseases. *Nat Commun*. 2017;8:1124.)

TABLE 303-1 EXAMPLES OF RECENTLY EMERGED AND REEMERGING ZOONOSES

DISEASE/ETIOLOGIC AGENT	TRANSMISSION	RESERVOIR HOST	CLINICAL MANIFESTATIONS
VIRUSES			
Bourbon virus	Ticks?	?	Fever, fatigue, rash, headache, myalgia, nausea, vomiting; leukopenia, thrombocytopenia
Heartland viruses	*Amblyomma americanum* tick bites	Deer?	Fever, headache, fatigue, anorexia, nausea, myalgia, arthralgia; thrombocytopenia, leukopenia
Zika virus	*Aedes aegypti* and *Aedes albopictus* mosquito bites	Nonhuman primates, sheep, bats, rodents	Rash, fever, arthralgia, conjunctivitis, myalgia, headache, retroorbital pain; congenital microcephaly, Guillain-Barré syndrome
Avian influenza (H5N1)	Inhalation	Poultry, wild and domestic waterfowl, other birds	Influenza-like illness, shortness of breath, difficulty breathing, viral pneumonia with or without acute respiratory distress syndrome, respiratory failure, multiorgan diseases
Hendra virus	Direct contact; horses	Flying fox	Fever, cough, sore throat, meningitis, encephalitis
Nipah virus	Contact, ingestion	Bats	Fever, headache, shortness of breath, difficulty breathing, encephalitis
BACTERIA AND RICKETTSIAE			
Q fever *Coxiella burnetii*	Indirect (aerosol) exposure	Goats, sheep, cattle, wildlife	Acute: fever, fatigue, photophobia, headache; cough with pneumonia; hepatitis; chronic: endocarditis, immunosuppression, chronic renal insufficiency
Spotted fever rickettsiosis Maculatum rickettsiosis *Rickettsia parkeri* Pacific Coast tick fever *Rickettsia philipii* 364D	*Amblyomma maculatum* ticks, *Dermacentor occidentalis* ticks	Small mammals, cattle? Small mammals	Fever, rash, eschar, myalgia, chills, fatigue, arthralgia, headache, lymphadenopathy Fever, headache, myalgia, arthralgia, malaise, lymphadenopathy (children), rash, eschar
Plague *Yersinia pestis*	Fleas	Small mammals	Fever, chills, headaches, carbuncles, lymphadenopathy with buboes, pneumonia, sepsis
PROTOZOA AND HELMINTHS			
Zoonotic malaria *Plasmodium knowlesi*	*Anopheles leucosphyrous* group mosquitoes	Macaques and monkeys	Fever, chills, headache, rigors, malaise, myalgia, cough, nausea, abdominal pain, vomiting, diarrhea
Babesiosis *Babesia microti*	*Ixodes scapularis* ticks	Small mammals	Fever, anemia, thrombocytopenia, elevated lactate dehydrogenase, hyperbilirubinemia, increased alanine aminotransferase and aspartate aminotransferase
Chagas disease *Trypanosoma cruzi*	Triatomine insects in *Triatoma*, *Rhodnius*, and *Panstrongylus* genera	Rodents, raccoons, skunks, coyotes	Chagoma (Romaña sign), fever, lymphadenopathy, edema, hepatosplenomegaly, myocarditis, meningoencephalitis; cardiomyopathy (arrhythmia, heart failure, atrioventricular/branch blocks, thromboembolism); gastrointestinal (dysperistalsis, megaesophagus, megacolon)
Baylisascariasis *Baylisascaris* spp	Ingestion of contaminated materials	Raccoons, skunks, badgers	Larva migrans (visceral, neural); diffuse unilateral subacute neuroretinitis
FUNGI			
Talaromycosis *Talaromyces (Penicillium) marneffei*	Direct contact, indirect contact?	Bamboo rats	Fever, cutaneous or subcutaneous lesion(s), malaise, anemia, dyspnea, weight loss, lymphadenopathy, nonproductive cough, anemia

DIAGNOSIS

The differentiation of zoonotic from nonzoonotic diseases is complex and challenging but often includes the same general diagnostic approaches. The key is to obtain sufficient historical details that might suggest a zoonotic exposure and which kind. Acquisition of information regarding potential exposure to animals must be thorough and should include occupation, travel, recreation, as well as pets (e.g., reptiles, exotic birds). The clinician should enquire about travel to suburban and rural areas, where ticks are generally more prevalent, as well as international travel. The patient should be asked about possible direct or indirect contact with animals, including bites and scratches, and exposure to vectors associated with zoonotic infection. Finally, the patient should be questioned about ingestion of specific food types associated with food-borne zoonoses, such as unpasteurized dairy products associated with *Brucella* and *Listeria*.

A careful physical examination, including a thorough skin evaluation of rashes, eschars, ulcers, or other lesions, is important. General laboratory and imaging studies as required can provide additional data. Depending on the specific suspected agent, confirmation of the etiology could require point-of-care nucleic acid testing,[16] blood culture, blood smear, paired acute and convalescent serology to document a four-fold rise in antibody titer, and/or molecular testing.[17] Mandatory reporting is required for some agents to protect the public's health. Some examples of zoonotic diseases included on the National Notifiable Infectious Diseases list for 2022 are anthrax (Chapter 272), babesiosis (Chapter 324), brucellosis (Chapter 286), campylobacteriosis (Chapter 279), Chikungunya virus disease (Chapter 352), cryptosporidiosis (Chapter 321), cyclosporiasis (Chapter 324), dengue (Chapter 352), ehrlichiosis and anaplasmosis (Chapter 302), hantavirus infection (Chapter 351), leptospirosis (Chapter 298), listeriosis (Chapter 272), malaria (Chapter 316), Q fever (Chapter 302), trichinellosis (Chapter 327), and Zika virus infection (Chapter 352).[18] Some tests are only available from large reference laboratories or at the U.S. Centers for Disease Control and Prevention.

TREATMENT

As diverse as they are, zoonoses will have specific treatments based on identification of the causative agent. This information is supplied in detail in the relevant chapters of this textbook.

PREVENTION

Prevention of zoonotic diseases requires use of personal protection (frequent handwashing, gloves, and disinfectants) to avoid direct contact with infected animals; application of insect repellent to minimize exposure to vectors and their bites; and avoidance of consumption of undercooked meats, unpasteurized dairy products, uncooked seafood, and tap water in areas of the world where sanitation is inadequate. For some diseases, vaccines are available, and individuals at risk because of occupation (e.g., farmers, veterinarians, forestry workers, microbiology laboratorians), recreation, or travel to endemic areas

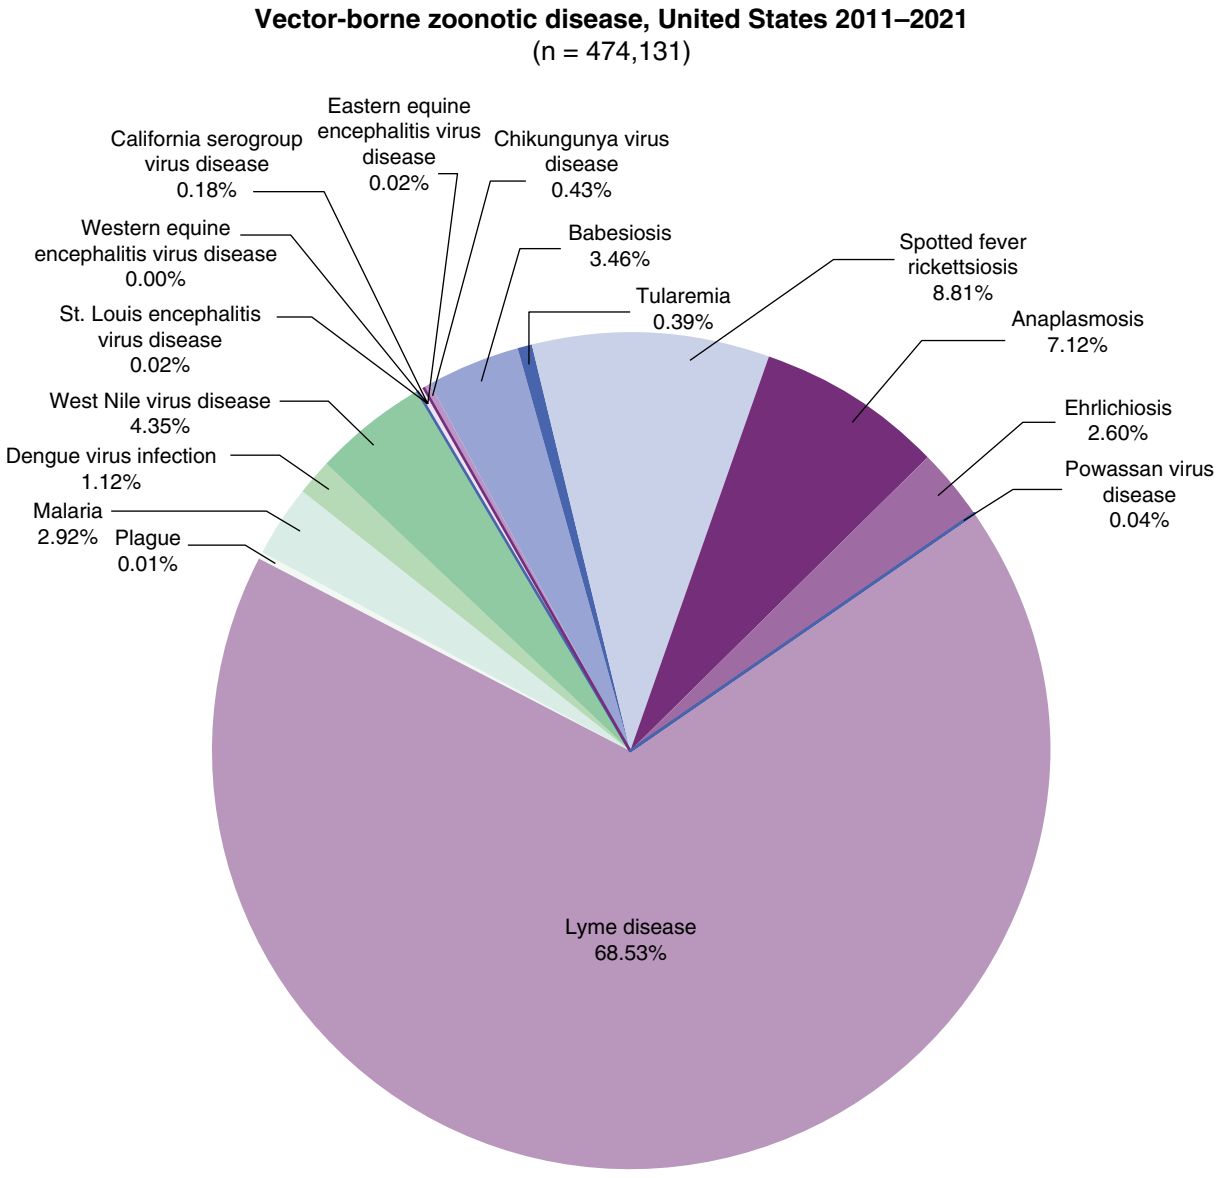

FIGURE 303-2. **Proportion of vector-borne zoonoses by pathogenic agent as reported to the U.S. Centers for Disease Control and Prevention in the United States between 2011 and 2021, except for Lyme disease and spotted fever rickettsiosis, for which data were available between 2011 and 2019; N = 474,131 cases.**

should be vaccinated. When possible, pets and domestic farm animals also should be vaccinated. Immunocompromised individuals who are potential hosts must be particularly careful.

Finally, some pathogens warrant patient isolation to prevent spread. Historically, this list has included hemorrhagic fever viruses (Chapter 351), Hantaviruses (Chapter 351), rabies (Chapter 383), severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) coronaviruses (Chapter 334), and anthrax (Chapter 272); however, the list has grown, and biocontainment units are increasingly required in tertiary care referral hospitals.

Examples of global strategies that have been proposed to have high impact on prevention of zoonotic infections include implementation of controls on wildlife trade and consumption, identification of land use conversions that most likely lead to emergence of zoonoses, and targeted global surveillance programs to identify novel pathogens of zoonotic potential before they emerge.[19]

PROGNOSIS

The prognosis of zoonoses is highly variable and dependent on the specific agent and disease. However, some zoonoses have high case fatality rates.

304 ACTINOMYCOSIS

ITZHAK BROOK

DEFINITION

Actinomycosis is an uncommon, subacute to chronic bacterial infection that induces both suppurative and granulomatous inflammation. Localized swelling with suppuration, abscess formation, tissue fibrosis, and draining sinuses characterize this disease. The infection spreads contiguously and often forms draining sinuses that extrude characteristic, but not pathognomonic, "sulfur granules." Infections of the oral and cervicofacial regions are the most common, but any site in the body can be infected, including the thoracic region, abdominopelvic region, and central nervous system (CNS). Musculoskeletal, cutaneous, or disseminated disease is rare but does occur. Actinomycosis sometimes mimics other diseases, particularly malignancy.

The Pathogen

Actinomycetes of the genera *Actinomyces*, *Propionibacterium*, and *Bifidobacterium* act as the principal pathogens. However, 98 to 99% of actinomycoses are caused

304 ACTINOMYCOSIS

ITZHAK BROOK

DEFINITION

Actinomycosis is an uncommon, subacute to chronic bacterial infection that induces both suppurative and granulomatous inflammation. Localized swelling with suppuration, abscess formation, tissue fibrosis, and draining sinuses characterize this disease. The infection spreads contiguously and often forms draining sinuses that extrude characteristic, but not pathognomonic, "sulfur granules." Infections of the oral and cervicofacial regions are the most common, but any site in the body can be infected, including the thoracic region, abdominopelvic region, and central nervous system (CNS). Musculoskeletal, cutaneous, or disseminated disease is rare but does occur. Actinomycosis sometimes mimics other diseases, particularly malignancy.

The Pathogen

Actinomycetes of the genera *Actinomyces*, *Propionibacterium*, and *Bifidobacterium* act as the principal pathogens. However, 98 to 99% of actinomycoses are caused

ABSTRACT

Actinomycosis is an uncommon, subacute to chronic bacterial infection that induces both suppurative and granulomatous inflammation. Localized swelling with suppuration, abscess formation, tissue fibrosis, and draining sinuses are characteristic. The infection spreads contiguously and often forms draining sinuses that extrude characteristic, but not pathognomonic, "sulfur granules." Infections of the oral and cervicofacial regions are the most common, but any site in the body can be infected, including the thoracic region, abdominopelvic region, and central nervous system. Musculoskeletal, cutaneous, or disseminated disease is rare but does occur.

KEYWORDS

actinomycosis

disseminated disease

by non–spore-forming anaerobic or microaerophilic bacterial species of the genus *Actinomyces*, family Actinomycetaceae, order Actinomycetales. Of the 49 *Actinomyces* spp, 26 may cause disease in humans: the strictly anaerobic *A. israelii, A. gerencseriae, A. odontolyticus, A. naeslundii, A. meyeri, A. viscosus, A. pyogenes,* and *A. georgiae. A. israelii* is the most common species causing human disease. *Pseudopropionibacterium propionicum* (formerly known as *Arachnia propionica*) and *Bifidobacterium dentium* (formerly known as *A. eriksonii*) also are associated with clinically indistinguishable infection.[1] The organisms are filamentous, branching, gram-positive, pleomorphic, non–spore-forming, non–acid-fast anaerobic, or microaerophilic bacilli. *Actinomyces* organisms are fastidious bacteria that require enriched culture media; 6 to 10% ambient CO_2 may aid in their growth, which takes up to 2 to 3 weeks in culture.

EPIDEMIOLOGY

Actinomyces spp are members of the endogenous mucous membrane flora in the oral cavity, lower gastrointestinal tract, bronchi, and female genital tract. No external environmental reservoir, such as soil or straw, has been documented, nor has person-to-person transmission of pathogenic *Actinomyces* spp been demonstrated. Although infection can occur in all age groups, it is rarely seen in children or patients older than 60 years. Most cases are encountered in individuals in the middle decades of life. A male-to-female infection ratio of 3:1 is reported in most series. The explanation for this ratio is the higher prevalence of poor oral hygiene and oral trauma in men. The annual reported incidence in the United States is fewer than 100 cases. However, because of the fastidious nature of the organism, many cases are undiagnosed, and the true incidence is probably much higher.

Oral and cervicofacial diseases are commonly associated with dental caries and extractions, gingivitis and gingival trauma, infection in erupting secondary teeth, chronic tonsillitis, otitis or mastoiditis, diabetes mellitus, immunosuppression, immunodeficiency, malnutrition, and neoplastic disease. Pulmonary infections generally arise after aspiration of oropharyngeal or gastrointestinal secretions and have been reported in patients with underlying lung disorders, such as emphysema, chronic bronchitis, and bronchiectasis. Gastrointestinal infection frequently follows loss of mucosal integrity, such as with surgery, trauma, foreign bodies, perforated appendix or diverticulitis, neoplasia, foreign bodies, and emergency colonic surgery. Extended use (>2 years) of intrauterine contraceptive devices (IUDs) increases risk for the development of actinomycosis of the female genital tract.

PATHOBIOLOGY

Actinomyces spp are agents of low pathogenicity and require mucosal barrier disruption to cause disease. Actinomycosis usually occurs in immunocompetent persons but may affect individuals with diminished host defenses. Risk factors include corticosteroids, bisphosphonates, leukemia with chemotherapy, human immunodeficiency virus (HIV), alcoholism, solid organ transplant, and local tissue damage caused by trauma, recent surgery, or irradiation.

Other bacterial species that are frequently copathogens with *Actinomyces* spp may assist in the spread of infection by inhibiting host defenses and reducing local oxygen tension. Once the organism is established locally, it may spread progressively to surrounding tissues. The infection tends to spread without regard for anatomic barriers, including fascial planes and lymphatic channels. The end result is a chronic, indurated, suppurative infection (usually with draining sinuses and fibrosis, especially in pelvic and abdominal infection). The fibrotic walls of the mass before suppuration are "wooden" in nature and may be confused with a neoplasm. Hematogenous spread can be fulminant but is rare.

Actinomyces spp grow in microscopic or macroscopic clusters of tangled filaments surrounded by neutrophils. Plasma cells and multinucleated giant cells are often observed with lesions, as are large macrophages with foamy cytoplasm around purulent centers. When visible, these clusters are pale yellow and exude through sinus tracts; they are called sulfur granules. These granules (1 to 2 mm in diameter) are made of aggregates of organisms and contain calcium phosphate. A central purulent loculation surrounds the granules. Their centers have a basophilic staining property, with eosinophilic rays terminating in pear-shaped "clubs." One to six granules can be present per loculation, and up to 50 loculations can be present in a lesion. Multicenter giant cells can be seen as well.

CLINICAL MANIFESTATIONS

Physicians must be aware of typical clinical manifestations, such as cervicofacial actinomycosis following a dental focus of infection, pelvic actinomycosis in women with an IUD, and pulmonary actinomycosis in smokers with poor dental hygiene.[2,3]

FIGURE 304-1. Actinomycosis of the jaw, observed at Letterman General Hospital, San Francisco, California, in a sergeant who had punctured the floor of his mouth while picking his teeth. (Courtesy Office of Medical History, Office of the Surgeon General, U.S. Army.)

Cervicofacial

Cervicofacial infection is the most common manifestation of actinomycosis (Fig. 304-1).[4,5] It is generally odontogenic and evolves as a chronic or subacute, painless or painful soft tissue infection that is characterized as a slowly progressive, nontender swelling or mass involving the submandibular or paramandibular region.[6] However, the submental and retromandibular spaces, temporomandibular joint, cheek, chin, and upper jaw can also be involved. The swelling may have a ligneous consistency caused by tissue fibrosis.

Depending on the composition of the concomitant synergistic flora, the onset of actinomycosis may be acute, subacute, or chronic. When *Staphylococcus aureus* (Chapter 267) or β-hemolytic streptococci (Chapter 269) are involved, an acute painful abscess or a phlegmatous cellulitis may be the initial manifestation. Pain and trismus can be disproportionate to the degree of inflammation apparent.

The chronic form of the disease is the most common presentation and is characterized by painless infiltration and bluish or reddish induration that generally progresses to form multiple abscesses and draining sinus tracts, which discharge pus that may contain sulfur granules in up to 25% of instances. Periapical infection, trismus, dyspnea, dysphagia, fever, pain, and leukocytosis may be present. The infection can extend to the carotid artery, tongue, nasal cavity,[7] sinuses, ears, mastoid, orbit, salivary glands, pharynx, masseter muscle, thyroid, larynx, trachea, or thorax. Bone (most commonly the mandible) may be invaded from the adjacent soft tissue, thereby resulting in periostitis or osteomyelitis. Cervical spine or cranial bone infection may lead to subdural empyema and invasion of the CNS. The differential diagnosis includes tuberculosis (scrofula) (Chapter 299), fungal infections (Chapter 308), nocardiosis (Chapter 306), suppurative infections by other organisms, and neoplasms.

Thoracic

Thoracic actinomycosis is an indolent, slowly progressive process involving the pulmonary parenchyma and pleural space.[8,9] This form accounts for 15 to 30% of actinomycosis cases and is caused by aspiration of infective material from the oropharynx (as well as rarely after esophageal perforation), by extension into the mediastinum from the neck, by spread from an abdominal site, or by hematogenous spread to the lung. Infection can spread from a pneumonic focus across lung fissures to involve the pleura and the chest wall, with eventual fistula formation and drainage containing sulfur granules (Fig. 304-2). The mediastinum, endocardium, and pericardium also rarely can be affected. Granules are seldom present in sputum. The incidence of this complication, as well as the destruction of thoracic vertebrae and adjacent ribs, has declined in the antimicrobial era.

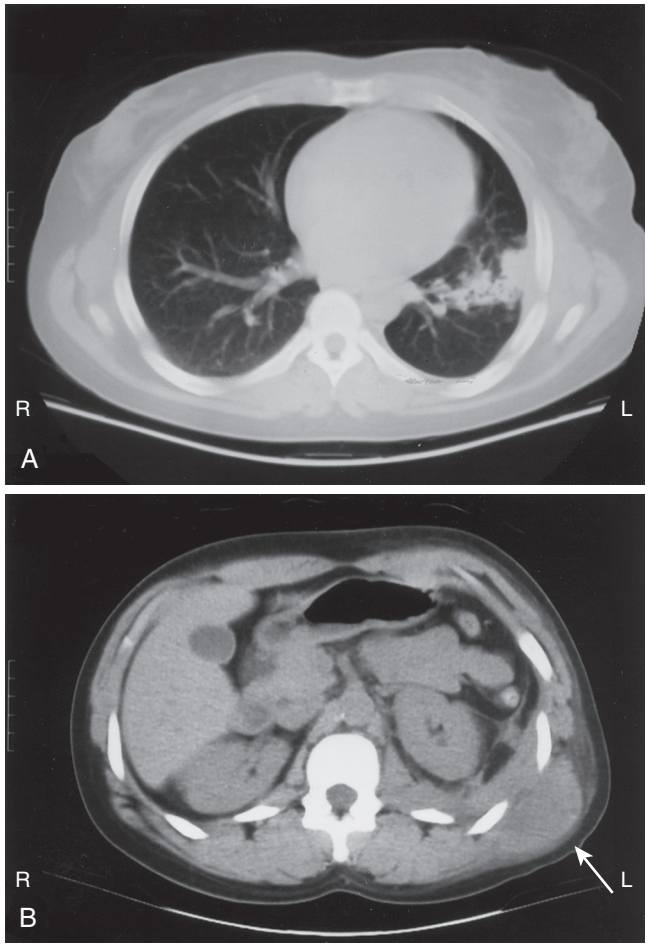

FIGURE 304-2. Thoracic computed tomography scan of a 43-year-old woman with pulmonary actinomycosis. A, There is consolidation of the lung with pleural thickening adjacent to the parenchymal disease. **B,** Abscess extended into the left breast and inferiorly to the costophrenic sulcus, to the retroperitoneum, and into the lateral abdominal wall (*arrow*).

The complaints of patients with thoracic actinomycosis are nonspecific, most commonly chest pain, productive cough, dyspnea, weight loss, and fever. Anemia, mild leukocytosis, and elevated sedimentation rate are relatively common. Patients often have a history of underlying lung disease and are rarely initially seen in an early stage of infection. The pulmonary lesion is either a mass lesion or pneumonitis and may resemble tuberculosis (Chapter 299), especially when cavity formation occurs, or blastomycosis, which may destroy ribs posteriorly but rarely forms sinuses. Nocardiosis (Chapter 306), aspergilloma (Chapter 311), bronchogenic carcinoma (Chapter 177), cryptococcosis (Chapter 309), aspiration pneumonia (Chapter 85), and lymphoma (Chapters 171 and 172) also can mimic thoracic actinomycosis. Pleural thickening, pleural effusion (Chapter 86), and emphysema are common.

Abdominal

Abdominal actinomycosis, which comprises approximately 20% of all cases of actinomycosis, is a chronic, localized inflammatory process that can occur weeks, months, or years after the integrity of the gastrointestinal mucosa is breached by surgery, cancer, or trauma. Abdominal infection also can be the result of direct extension from the thorax or pelvis or of hematogenous dissemination.[10] The ileocecal region is involved most frequently (usually after a perforated appendix), often with the formation of a mass lesion.[11] The infection extends slowly to contiguous organs, especially the liver, and may involve retroperitoneal tissues, the spine, or the abdominal wall. Hepatic, renal, or splenic dissemination is an uncommon complication. Persistent draining sinuses may form, and sinuses involving the perianal region[12] can simulate Crohn disease (Chapter 127) or tuberculosis (Chapter 299). The extensive fibrosis of actinomycotic lesions, recognized by the examiner as a mass, often suggests tumor. A frequent finding on computed tomography (CT) is an infiltrative mass with dense inhomogeneous contrast medium enhancement. Constitutional symptoms and signs are nonspecific, the most common being fever, diarrhea or constipation, weight loss, nausea, vomiting, pain, and the sensation of a mass.

Pelvic

Pelvic infection can occur in patients with prolonged use of IUDs and also may occur from extension of intestinal infection, commonly from indolent ileocecal disease.[13] Manifestations may range from a chronic vaginal discharge to pelvic inflammatory disease (Chapter 264) with tubo-ovarian abscesses or pseudomalignant masses. Patients generally have abnormal vaginal bleeding or discharge, abdominal or pelvic pain, menorrhagia, fever, and weight loss.

Endometritis is the earlier form of the infection, followed by tubo-ovarian abscesses. Extension to the uterus, bladder, rectal area, abdominal wall, peritoneum, pelvic bones, thorax, and systemic circulation also can occur.

Central Nervous System

Infections of the CNS are very rare and generally manifest as single or multiple encapsulated brain abscesses (Chapter 382)[14] that appear as ring-enhancing lesions with a thick wall that may be irregular or nodular on contrast-enhanced CT scans. No features readily distinguish actinomycosis from other causes of chronic brain abscesses. Rarely, solid nodular or mass lesions termed *actinomycetomas* or *actinomycotic granulomas* are found.[15] Headache and focal neurologic signs are the most common findings. Most actinomycotic infections of the CNS are seeded hematogenously from a distant primary site, but direct extension of cervicofacial disease also occurs. Sinus formation is not characteristic of CNS disease. Meningitis (Chapter 381) caused by *Actinomyces* may be misdiagnosed as tuberculous meningitis because it is chronic and basilar in location, and the cerebrospinal fluid pleocytosis is usually lymphocytic. The meningitis of actinomycosis is characteristically a pachymeningitis that involves thickening of the dura mater. Extension to the cranial epidural or subdural space and spinal epidural space also can occur from adjacent foci.

DIAGNOSIS

Appropriate microbiologic and pathologic studies are essential for diagnosis. A high index of suspicion should be communicated to the microbiology laboratory, along with material from draining sinuses, from deep-needle aspiration, or from biopsy specimens. CT or ultrasound needle aspiration can be used to obtain a biopsy specimen. It is important to avoid contamination of the specimen by normal flora and administration of antimicrobial therapy before specimens are obtained. Multiple biopsy sections from different tissue levels are recommended to improve the histopathologic diagnosis.

The presence, in pus or tissue specimens, of non–acid-fast, gram-positive organisms with filamentous branching is suggestive of the diagnosis. Direct testing of clinical specimens can facilitate identification by using specific polymerase chain reaction probes, staining with fluorescent-conjugated monoclonal antibodies, and matrix-assisted laser desorption ionization time-of-flight mass spectrometry.[16]

The characteristic morphologic features of sulfur granules within are also helpful. In tissue sections stained with hematoxylin-eosin, sulfur granules are round or oval basophilic masses with a radiating arrangement of eosinophilic terminal clubs. However, *Actinomyces* spp are infrequently visible in sections stained with hematoxylin-eosin; visualization is facilitated by special stains such as Gomori methenamine silver, *p*-aminosalicylic acid, McCallen-Goodpasture, and Brown-Brenn. The granules must be distinguished from similar structures that are sometimes produced in infections caused by *Nocardia, Monosporium, Cephalosporium, Staphylococcus* (botryomycosis), and other organisms.

Actinomyces and *Arachnia* can generally be differentiated from other gram-positive anaerobes by means of their slow growth rate production of catalase and by gas-liquid chromatography. Anaerobic culture is required to grow the organism, and no selective media are available to restrict overgrowth of the slow-growing *Actinomyces* by associated microflora.

Most actinomycotic infections are polymicrobial and involve other aerobic and anaerobic bacteria. The most common co-isolates depend on the infection site and are *Actinobacillus actinomycetemcomitans, Aggregatibacter aphrophilus, Eikenella corrodens, Bacteroides, Fusobacterium, Capnocytophaga*, aerobic and anaerobic streptococci, *Staphylococcus*, and Enterobacteriaceae.

Imaging methods such as conventional radiography, CT, and magnetic resonance imaging do not provide a specific diagnosis.[17] However, they are often critical for accurate definition of the dimensions and extension of the infection, as well as to monitor the efficacy of therapy.

TREATMENT

Adequate local drainage is indicated if abscesses are present. Surgical removal of infected tissue also may be necessary in some cases, especially if extensive necrotic tissue or fistulas are present, if malignant disease cannot be excluded, and if large abscesses cannot be drained by percutaneous aspiration.

Penicillin G is the drug of choice for treatment of an infection caused by any of the *Actinomyces*. Most deep-seated infections can be expected to respond to intravenous penicillin G (3 to 4 million units every 4 hours, given for 2 to 6 weeks) followed by an oral phenoxypenicillin (2 to 4 g/day). A few additional weeks of oral penicillin therapy may suffice for uncomplicated cervicofacial disease, but complicated cases and extensive pulmonary or abdominal disease may require treatment for 12 to 18 months. Little evidence exists of acquired resistance to penicillin G by *Actinomyces* during prolonged therapy. The combination of a penicillin (i.e., amoxicillin, piperacillin) and a β-lactamase inhibitor (i.e., clavulanate, tazobactam) offers the advantage of coverage against penicillin-resistant aerobic and anaerobic copathogens. For example, clinical and microbiologic cure is achieved in >85% of cases of cutaneous actinomycosis with amoxicillin/clavulanic acid 875/125 mg orally, twice daily for up to 12 weeks. Alternative first-line antibiotics include amoxicillin alone (500 mg orally four times daily) for up to 12 weeks, tetracycline (500 mg orally four times daily for up to 12 weeks), erythromycin (500 to 1000 mg intravenously or 500 mg orally four times daily for up to 12 weeks), and clindamycin (500 mg intravenously or 300 to 450 mg orally four times daily, for up to 12 weeks). Ceftriaxone, imipenem, and fluoroquinolones have also been used successfully. Metronidazole, aminoglycosides, oxacillin, and cephalexin are not effective. In vitro antimicrobial susceptibility testing of *Actinomyces* is difficult, and the results may not be predictive of antimicrobial effects in vivo.

Whether treatment of co-isolates is warranted depends on the organism and site of infection. Treatment of coexisting *S. aureus* (Chapter 267), *Proteus* (Chapter 282), and *Pseudomonas* (Chapter 282) is always warranted, and antimicrobial coverage for other known pathogens also is appropriate, especially for invasive and lower abdominal infections.

When well-defined IUD-related symptoms and Papanicolaou smears demonstrate *Actinomyces* by specific fluorescence-labeled antibody, the IUD should be removed. Antimicrobial administration for a 2-week period may be indicated. More serious infections require prolonged therapy.

PROGNOSIS

The availability of antimicrobial treatment has greatly improved the prognosis for all forms of actinomycosis. At present, cure rates are high, and neither deformity nor death is common.

305 WHIPPLE DISEASE

THOMAS RUDOLF SCHNEIDER

DEFINITION

Whipple disease is a rare chronic systemic infection that is caused by *Tropheryma whipplei* and is characterized by a wide range of symptoms including fever, diarrhea, malabsorption, weight loss, arthralgias, arthritis, central nervous system involvement, lymphadenopathy, and serositis. *T. whipplei* can also cause asymptomatic infection, acute transient infections, and isolated endocarditis or pneumonia.

The Pathogen

T. whipplei is a gram-positive, slowly replicating, rod-shaped bacterium, 0.25 × 1.5 to 2.5 μm in length and surrounded by a trilaminar plasma membrane and a homogenous 20-nm-thick cell wall. Replication of *T. whipplei* is very slow, with a doubling time of about 17 days. The genome of *T. whipplei* is small (925 kilobases) with a single circular chromosome and considerable sequence variation. The organism's lack of key biochemical pathways contributes to dependence on the host for replication. The organism is phylogenetically in the actinomycetes subdivision and similar to actinobacteria and nocardioforms.

EPIDEMIOLOGY

Classical Whipple disease occurs rarely. The incidence is less than 1 per million, and the prevalence is approximately 3 per million in Europe and 10 per million in the United States.[1] In the United States, Whipple disease accounts for about 4 to 5 per million hospitalizations.[2] It is even more rare in Asia and rather unknown in Africa. White middle-aged males appear to be more commonly affected. In a German cohort, for example, 77% of patients were men, and the mean age at diagnosis was 57 years. Humans are the only identified host for *T. whipplei*. Environmental reservoirs include water and sewage, and humans presumably are exposed through contaminated drinking water. *T. whipplei* has been identified in human saliva and feces.

PATHOBIOLOGY

The pathobiology ranges from asymptomatic colonization of the oropharynx and gastrointestinal tracts to disseminated disease. *T. whipplei* has been identified in macrophages in the small intestine, polymorphonuclear leukocytes, mast cells, plasma cells, and endothelial and epithelial cells. It is likely that bacteria replicate in the digestive system, are phagocytized by macrophages, and then replicate in peripheral blood mononuclear cells and macrophages. Infection of the lamina propria of the small bowel leads to diarrhea, abdominal pain, bloating, malabsorption, and weight loss. Dissemination of the organism through the blood and lymphatic system leads to infection of the central nervous system, lymph nodes, heart valves, lungs, and other organs. Overall, about 2 to 4% of the population are asymptomatic carriers of *T. whipplei*, a percentage that dwarfs the low estimated prevalence of classical Whipple disease, thereby suggesting that an underlying genetic or immunologic predisposition is likely necessary for an individual to develop classical Whipple disease. Dysfunction of immune cells, including T cells, macrophages, plasma cells, and dendritic cells, is associated with the development of Whipple disease. Multifactorial predisposition towards the development of Whipple disease has been reportedly related to specific human leukocyte antigen (HLA) associations (e.g., DRB1*13 and DQB1*6, but not B27) or polymorphisms within certain cytokine genes. Patients with classic Whipple disease have reduced $CD4^+$ T-cell responses against the organism, thereby leading to multisystem disease.

In classical Whipple disease, uncontrolled bacterial replication and mucosal destruction results in translocation of the bacteria from the gastrointestinal tract into the blood stream, with subsequent development of systemic infection. Pathology demonstrates edematous, thick, flattened, and widened villi of the duodenum and jejunum. On microscopy, yellow lipid deposits are visible, and foamy granular periodic acid–Schiff (PAS)–positive inclusions are seen in the lamina propria. PAS-positive macrophages and *T. whipplei* nucleic acid (on polymerase chain reaction [PCR] testing) can be detected in many organs, body fluids, and tissues including liver, spleen, lymph nodes, synovium, bone marrow, heart, lung, central nervous system (CNS), and cerebrospinal fluid. Other pathologic manifestations include organomegaly, polyserositis, and CNS demyelination.

CLINICAL MANIFESTATIONS

The clinical spectrum of diseases is categorized as asymptomatic carriage, transient and acute infections, localized infections, classical and systemic Whipple disease, and Whipple disease associated with immunosuppression.

Asymptomatic Infection

Healthy asymptomatic persons can carry *T. whipplei* in their oropharyngeal and gastrointestinal tract and shed the organism in their saliva and stool. The highest incidence of asymptomatic carriage occurs in rural regions of sub-Saharan Africa (about 30% in stool and 3.5% in saliva).[3] In Europe, *T. whipplei* has been identified in stool samples of 1 to 11% of healthy adults. Stool carriage is more common in sewage workers (12 to 26%).

Imaging methods such as conventional radiography, CT, and magnetic resonance imaging do not provide a specific diagnosis.[17] However, they are often critical for accurate definition of the dimensions and extension of the infection, as well as to monitor the efficacy of therapy.

TREATMENT

Adequate local drainage is indicated if abscesses are present. Surgical removal of infected tissue also may be necessary in some cases, especially if extensive necrotic tissue or fistulas are present, if malignant disease cannot be excluded, and if large abscesses cannot be drained by percutaneous aspiration.

Penicillin G is the drug of choice for treatment of an infection caused by any of the *Actinomyces*. Most deep-seated infections can be expected to respond to intravenous penicillin G (3 to 4 million units every 4 hours, given for 2 to 6 weeks) followed by an oral phenoxypenicillin (2 to 4 g/day). A few additional weeks of oral penicillin therapy may suffice for uncomplicated cervicofacial disease, but complicated cases and extensive pulmonary or abdominal disease may require treatment for 12 to 18 months. Little evidence exists of acquired resistance to penicillin G by *Actinomyces* during prolonged therapy. The combination of a penicillin (i.e., amoxicillin, piperacillin) and a β-lactamase inhibitor (i.e., clavulanate, tazobactam) offers the advantage of coverage against penicillin-resistant aerobic and anaerobic copathogens. For example, clinical and microbiologic cure is achieved in >85% of cases of cutaneous actinomycosis with amoxicillin/clavulanic acid 875/125 mg orally, twice daily for up to 12 weeks. 305 WHIPPLE DISEASE

THOMAS RUDOLF SCHNEIDER

DEFINITION

Whipple disease is a rare chronic systemic infection that is caused by *Tropheryma whipplei* and is characterized by a wide range of symptoms including fever, diarrhea, malabsorption, weight loss, arthralgias, arthritis, central nervous system involvement, lymphadenopathy, and serositis. *T. whipplei* can also cause asymptomatic infection, acute transient infections, and isolated endocarditis or pneumonia.

The Pathogen

T. whipplei is a gram-positive, slowly replicating, rod-shaped bacterium, 0.25 × 1.5 to 2.5 μm in length and surrounded by a trilaminar plasma membrane and a homogenous 20-nm-thick cell wall. Replication of *T. whipplei* is very slow, with a doubling time of about 17 days. The genome of *T. whipplei* is small (925 kilobases) with a single circular chromosome and considerable sequence variation. The organism's lack of key biochemical pathways contributes to dependence on the host for replication. The organism is phylogenetically in the actinomycetes subdivision and similar to actinobacteria and nocardioforms.

EPIDEMIOLOGY

Classical Whipple disease occurs rarely. The incidence is less than 1 per million, and the prevalence is approximately 3 per million in Europe and 10 per million in the United States.[1] In the United States, Whipple disease accounts for about 4 to 5 per million hospitalizations.[2] It is even more rare in Asia and rather unknown in Africa. White middle-aged males appear to be more commonly affected. In a German cohort, for example, 77% of patients were men, and the mean age at diagnosis was 57 years. Humans are the only identified host for *T. whipplei*. Environmental reservoirs include water and sewage, and humans presumably are exposed through contaminated drinking water. *T. whipplei* has been identified in human saliva and feces.

PATHOBIOLOGY

The pathobiology ranges from asymptomatic colonization of the oropharynx and gastrointestinal tracts to disseminated disease. *T. whipplei* has been identified in macrophages in the small intestine, polymorphonuclear leukocytes, mast cells, plasma cells, and endothelial and epithelial cells. It is likely that bacteria replicate in the digestive system, are phagocytized by macrophages, and then replicate in peripheral blood mononuclear cells and macrophages. Infection of the lamina propria of the small bowel leads to diarrhea, abdominal pain, bloating, malabsorption, and weight loss. Dissemination of the organism through the blood and lymphatic system leads to infection of the central nervous system, lymph nodes, heart valves, lungs, and other organs. Overall, about 2 to 4% of the population are asymptomatic carriers of *T. whipplei*, a percentage that dwarfs the low estimated prevalence of classical Whipple disease, thereby suggesting that an underlying genetic or immunologic predisposition is likely necessary for an individual to develop classical Whipple disease. Dysfunction of immune cells, including T cells, macrophages, plasma cells, and dendritic cells, is associated with the development of Whipple disease. Multifactorial predisposition towards the development of Whipple disease has been reportedly related to specific human leukocyte antigen (HLA) associations (e.g., DRB1*13 and DQB1*6, but not B27) or polymorphisms within certain cytokine genes. Patients with classic Whipple disease have reduced $CD4^+$ T-cell responses against the organism, thereby leading to multisystem disease.

In classical Whipple disease, uncontrolled bacterial replication and mucosal destruction results in translocation of the bacteria from the gastrointestinal tract into the blood stream, with subsequent development of systemic infection. Pathology demonstrates edematous, thick, flattened, and widened villi of the duodenum and jejunum. On microscopy, yellow lipid deposits are visible, and foamy granular periodic acid–Schiff (PAS)–positive inclusions are seen in the lamina propria. PAS-positive macrophages and *T. whipplei* nucleic acid (on polymerase chain reaction [PCR] testing) can be detected in many organs, body fluids, and tissues including liver, spleen, lymph nodes, synovium, bone marrow, heart, lung, central nervous system (CNS), and cerebrospinal fluid. Other pathologic manifestations include organomegaly, polyserositis, and CNS demyelination.

CLINICAL MANIFESTATIONS

The clinical spectrum of diseases is categorized as asymptomatic carriage, transient and acute infections, localized infections, classical and systemic Whipple disease, and Whipple disease associated with immunosuppression.

Asymptomatic Infection

Healthy asymptomatic persons can carry *T. whipplei* in their oropharyngeal and gastrointestinal tract and shed the organism in their saliva and stool. The highest incidence of asymptomatic carriage occurs in rural regions of sub-Saharan Africa (about 30% in stool and 3.5% in saliva).[3] In Europe, *T. whipplei* has been identified in stool samples of 1 to 11% of healthy adults. Stool carriage is more common in sewage workers (12 to 26%).

ABSTRACT

Whipple disease is a rare chronic systemic infection caused by *Tropheryma whipplei*. The incidence of classical Whipple disease is less than 1 per million, and the prevalence is approximately 3 per million in Europe and 10 per million in the United States. It is even more rare in Asia and rather unknown in Africa. The pathobiology ranges from asymptomatic colonization of the oropharynx and gastrointestinal tracts to disseminated disease. *T. whipplei* has been identified in macrophages in the small intestine, polymorphonuclear leukocytes, mast cells, and plasma cells, as well as in endothelial and epithelial cells. Infection of the lamina propria of the small bowel leads to diarrhea, abdominal pain, bloating, malabsorption, and weight loss. In classical Whipple disease, dissemination of the organism via the blood stream or lymphatic system leads to a wide range of symptoms, including fever, arthralgias, arthritis, central nervous system involvement, lymphadenopathy, and serositis. *T. whipplei* can also cause asymptomatic infection, acute transient infections, and isolated endocarditis or pneumonia. Classical Whipple disease is fatal without treatment, but effective antibiotic treatments significantly improve outcomes.

TABLE 305-1 MAJOR SYMPTOMS OF CLASSICAL WHIPPLE DISEASE

SYMPTOM	AFFECTED PATIENTS (%)
Weight loss	85-95
Anemia	80-90
Arthropathy	70-85
Diarrhea	70-80
Abdominal pain	55-60
Lymphadenopathy	45-60
Fever	40-45
Hyperpigmentation	35-45
CNS involvement	10-40
Ocular signs	5-10

CNS = central nervous system.

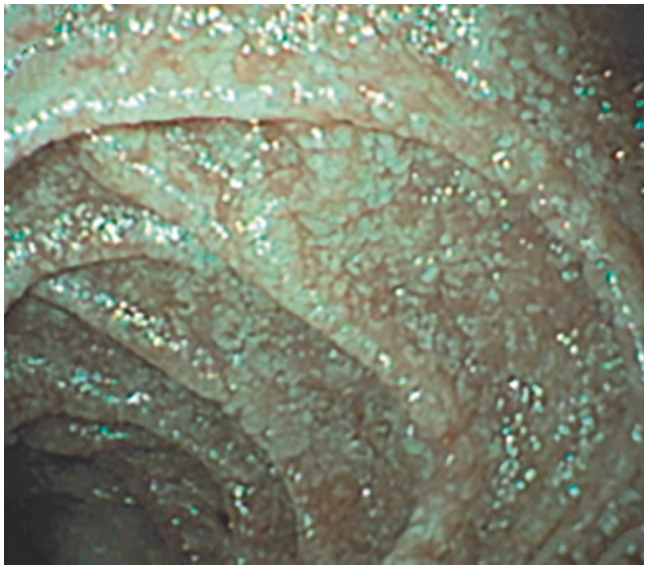

FIGURE 305-1. Characteristic appearance of the duodenal mucosa and classical diagnosis of Whipple disease from the duodenum. Macroscopic view at endoscopy of a heavily affected case with clumsy and dilated villi with ecstatic lymph vessels. (From Schneider T, Moos V, Loddenkemper C, et al. Whipple's disease: new aspects of pathogenesis and treatment. *Lancet Infect Dis*. 2008;8:179-190.)

Transient and Acute Infection

T. whipplei may cause acute gastroenteritis in children, most commonly in Africa and France, and 15% of young children with diarrhea in one study had *T. whipplei*. In addition to diarrhea, acute infection can be associated with bacteremia and cough. *T. whipplei* has been identified on bronchoalveolar lavage in 3% of HIV-positive patients with pneumonia.

Localized infection most commonly presents as culture-negative bacterial endocarditis (Chapter 61), with slowly degenerating valvular lesions.[4] In one German cohort of patients with culture-negative endocarditis without classical Whipple disease, *T. whipplei* was the most common agent identified.

Classical Whipple Disease

The clinical spectrum of classical Whipple disease (Table 305-1) may be quite variable based on the stage of disease, the organs involved, and the host's underlying characteristics. The uncontrolled bacterial replication and systemic infection of classical Whipple disease cause severe disseminated disease.

Gastrointestinal manifestations, including diarrhea, abdominal pain, bloating, malabsorption, and associated weight loss, are common. Chronic diarrhea may progress to severe cachexia, with resulting hypoproteinemia, ascites, and peripheral edema.

Common systemic manifestations include arthralgias, arthritis, neurologic manifestations, low-grade intermittent fever, night sweats, and lymphadenopathy. Chronic, nonproductive cough, polyserositis, and organomegaly may occur. Skin hyperpigmentation has been reported.

In about 70% of patients, joint symptoms may have been present for many years and misdiagnosed as seronegative rheumatoid arthritis.[5] Nondestructive, migratory, seronegative arthralgia and arthritis typically involve the peripheral joints and are often associated with myalgias.[6]

The most serious manifestations involve the CNS.[7] Rare progressive supranuclear ophthalmoplegia with oculomasticatory myorhythmia or oculofacioskeletal myorhythmia are considered pathognomonic for CNS Whipple disease. Other symptoms include cognitive dysfunction, ataxia, headache, insomnia, seizures, meningitis, and involvement of the peripheral nerves and spinal cord. Ocular involvement, such as uveitis, affects 11% of cases.

Whipple disease associated with immunosuppression can occur when patients with undiagnosed disease receive tumor necrosis factor blocker therapy, thereby accelerating the course of the disease from local symptoms to systemic disease. Immunosuppressive therapy may also exacerbate diarrhea or lead to endocarditis or CNS disease.

DIAGNOSIS

The diagnosis of Whipple disease can be difficult because of its nonspecific nature and multisystem manifestations. Diagnosis is often delayed and requires a high index of suspicion. The differential diagnosis of Whipple disease is large and includes a number of diseases such as seronegative rheumatoid arthritis (Chapter 243), sarcoidosis (Chapter 83), celiac disease (Chapter 126), tropical sprue (Chapter 126), Crohn disease (Chapter 127) with reactive arthritis, and a variety of neurologic diseases.

Classical Whipple disease usually can be diagnosed on duodenal biopsies. Multiple deep biopsies are indicated. Duodenal endoscopic features include a pale yellow mucosal surface with disordered dilated villi (Fig. 305-1). Ectatic lymph vessels may also be present (Fig. 305-2A). However, macroscopic changes are absent in the majority of cases. The hallmark of classical Whipple disease is the accumulation of foamy macrophages filled with *T. whipplei* in the duodenal mucosa detected by PAS staining (Fig. 305-2B). PAS-positive cells may persist for years within the tissues, but PAS-staining fades and the number of PAS-positive macrophages decreases during treatment.

Duodenal histology may be positive even in the absence of gastrointestinal symptoms, but a negative duodenal biopsy does not exclude the disease in suspected cases, especially in the absence of diarrhea. In such cases, biopsies from alternative tissues (e.g., the CNS, lymph nodes, muscles, joints, synovium, eyes, lung, or excised heart valves) can establish gastrointestinal infection (Fig. 305-3).

PCR testing is useful for diagnosis and follow-up.[8] PCR testing is preferred for sterile body fluids such as cerebrospinal fluid (CSF), synovial fluid, ascites, pleural effusion, or brain biopsies. PCR from CSF should be routinely performed, because asymptomatic CNS infection occurs in up to 50% of patients, and eradication of the agent from the CNS is essential to guide proper treatment. High-volume positive PCR in feces (above 32,500 copies/mL) is strongly associated with clinical disease,[9] but the normal carriage of *T. whipplei* in otherwise healthy individuals means that an isolated positive PCR from oral, gastrointestinal, stool, or bronchial specimens does not ensure the diagnosis (see Fig. 305-3).

PCR usually becomes negative shortly after appropriate antibiotic treatment, so a negative PCR in an antibiotic pretreated patient is not helpful. In patients treated with antibiotics, *T. whipplei*–specific immunohistochemistry is preferred because it remains positive and detects *T. whipplei* within the tissue after antibiotic treatment.

TREATMENT

Without appropriate treatment, Whipple disease can be fatal. Initial intravenous induction therapy is recommended with ceftriaxone (2 g intravenously [IV] daily for 2 weeks for general therapy but 2 g IV daily for 4 weeks for CNS disease or endocarditis) followed by at least 1 year of trimethoprim/sulfamethoxaxole (160/800 mg orally twice daily). Equally good alternatives are 4 weeks of meropenem (1 g IV three times per day) for CNS infection or penicillin G (10 million total units IV daily) for endocarditis.[10]

Some data also suggest that 2 weeks of 2 g of IV ceftriaxone followed by 3 months of trimethoprim-sulfamethoxazole is equally good for all types of infection. In cases of allergy or relapse, doxycycline (100 mg twice daily) plus hydroxychloroquine (200 mg orally three times daily) for 1 year followed by

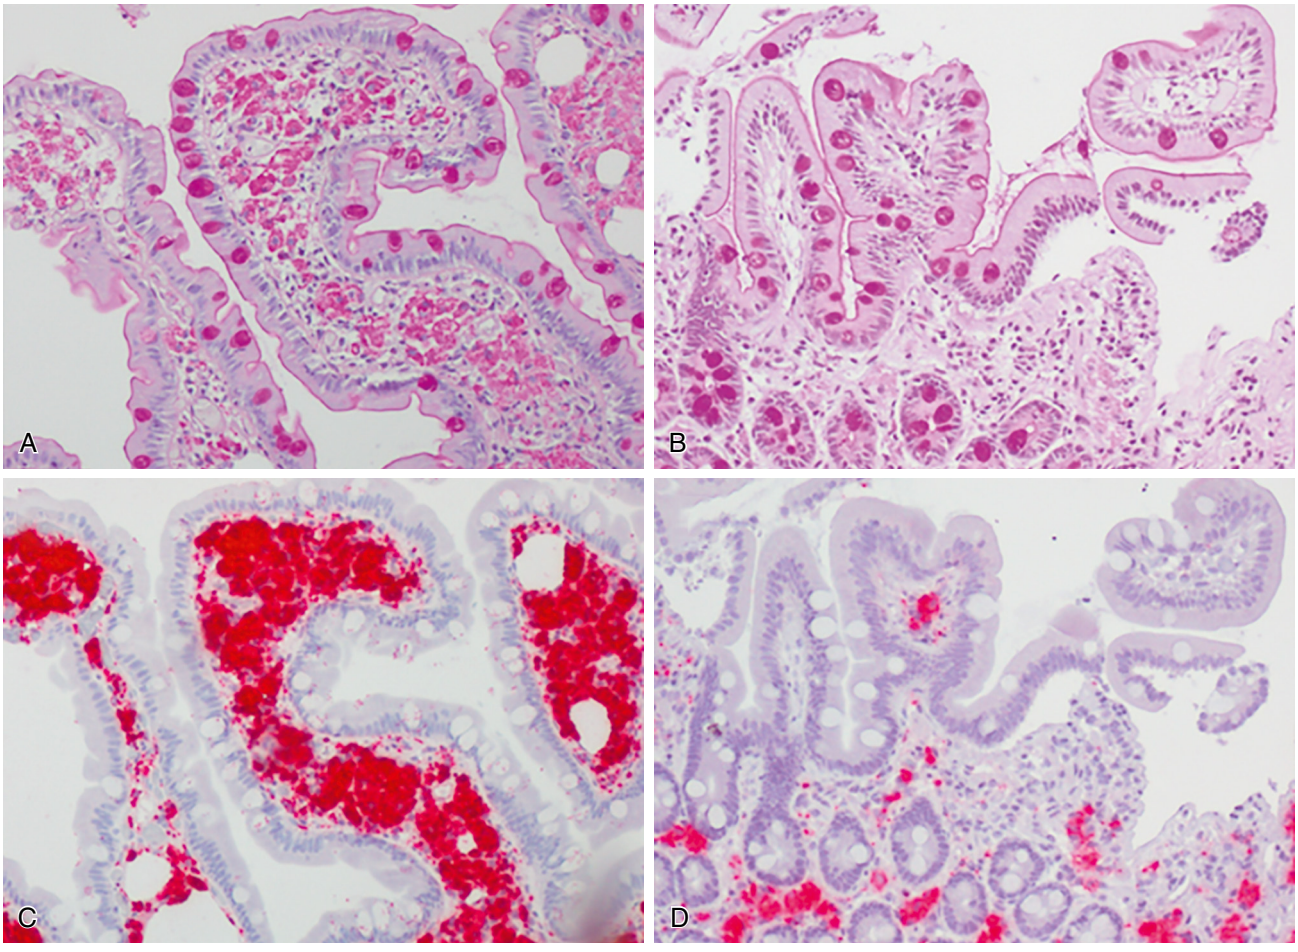

FIGURE 305-2. **Characteristic (A) and very weak (B) periodic acid–Schiff (PAS) staining and corresponding *T. whipplei*–specific immunohistochemistry (C, D) of duodenal biopsies of two untreated Whipple disease patients. A, C,** Duodenal mucosa with typical histologic appearance with flattened villi and lymphangiectasia, PAS-positive sickle particle–containing (SPC) cells, and strong immunohistochemical staining within the villi. **B, D,** Biopsies of a patient without typical PAS staining but evidence of *T. whipplei* infection by positive specific immunohistochemistry, especially in deeper regions of the mucosa around the crypts.

lifelong treatment with doxycycline (200 mg/day) is recommended. If these options are not tolerated, penicillin, minocycline, chloramphenicol, or antibiotic combinations can be used under expert supervision.

In about 10% of cases, treatment is complicated by an immune reconstitution inflammatory syndrome, with recurrence of inflammation and symptoms in the absence of other detectable causes. The risk for immune reconstitution inflammatory syndrome is increased in patients who were receiving immunosuppressive therapy prior to the diagnosis of Whipple disease.[11] For severe or life-threatening symptoms, treatment with corticosteroids can be effective (e.g., 1 mg/kg/daily until acute symptoms improve followed by reductions of 5 to 10 mg every 2 to 3 weeks, then a slow taper from 10 mg to zero). Some patients may require a slower taper or a 5-mg daily dose for several months.

PREVENTION

Currently, no prevention strategies are recommended. Lifelong antibiotic treatment is not recommended.

PROGNOSIS

Classical Whipple disease with systemic manifestations is always eventually fatal without treatment, but mortality is usually below 5% with treatment. Appropriate treatment improves symptoms rapidly, and most cases achieve clinical remission. Diarrhea and fever often resolve within a few days, whereas the recovery from arthritis and neurologic symptoms can take weeks. CNS manifestations may progress and ultimately lead to death despite ongoing antibiotic treatment.

Relapses or reinfection after adequate therapy is very rare, but lifelong clinical follow-up is recommended for all patients. Given the complexity of diagnosis, treatment, and long-term management, clinicians experienced in the management of Whipple disease should be involved in the care of these patients.

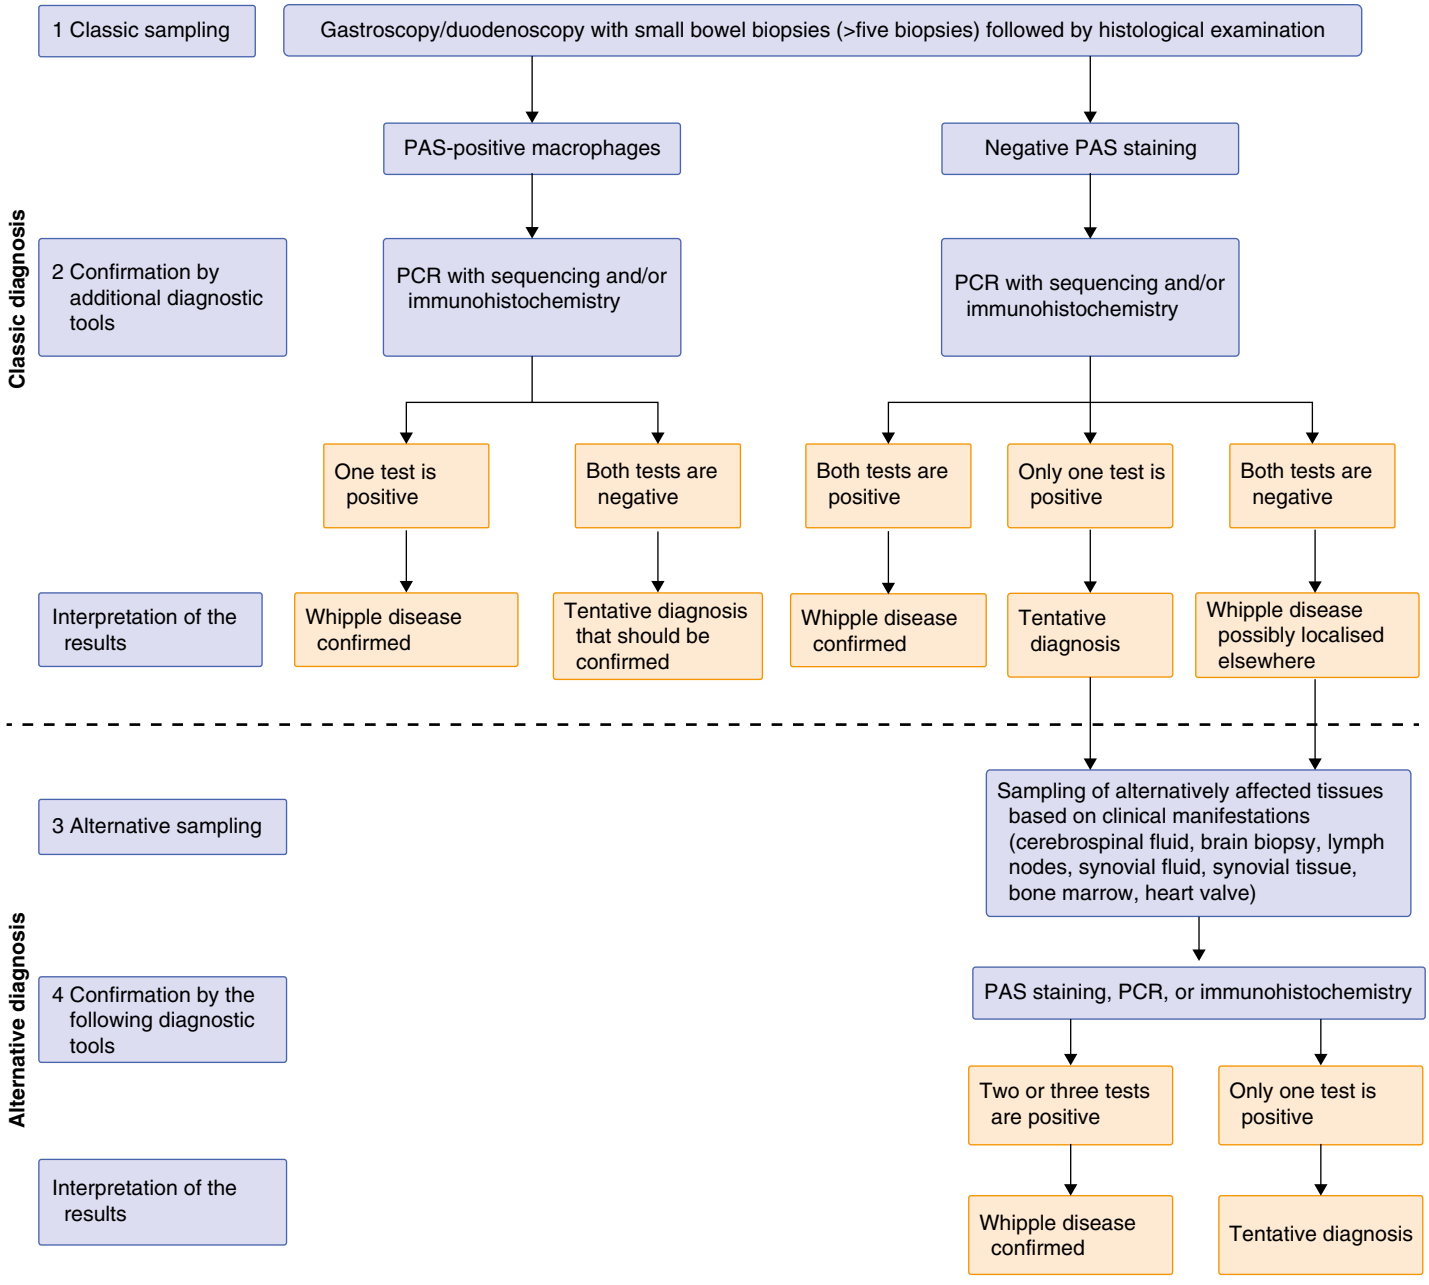

FIGURE 305-3. Hierarchic scheme for the diagnosis of Whipple disease based on clinical symptoms. PAS = periodic acid–Schiff; PCR = polymerase chain reaction. (From Schneider T, Moos V, Loddenkemper C, et al. Whipple's disease: new aspects of pathogenesis and treatment. *Lancet Infect Dis*. 2008;8:179-190.)

306 NOCARDIOSIS

FREDERICK S. SOUTHWICK

DEFINITION

Nocardiosis refers to infections caused by *Nocardia* spp. *Nocardia* most commonly causes pneumonia but also can infect the central nervous system (CNS) and the skin. Less commonly, this organism can disseminate throughout the body. These infections usually occur in immunosuppressed patients.

The Pathogen

Nocardia spp are thin, aerobic, gram-positive bacilli that form branching filaments.[1] The bacteria stain irregularly and appear beaded on Gram stain and positive on modified acid-fast stain. The species are now identified by gene sequencing and DNA-DNA hybridization. The number of species causing human disease is large and includes *N. abscessus, N. brevicatena/paucivorans* complex, *N. nova* complex, *N. transvalensis* complex, *N. farcinica, N. cyriacigeorgica, N. otitidiscaviarum, N. veterana, N. brasiliensis*, and *N. pseudobrasiliensis*.

EPIDEMIOLOGY

Nocardia spp are ubiquitous and primarily originate in soil. Despite being found throughout the environment, they rarely cause symptomatic infection in humans. Because nocardiosis is not a reportable disease, the frequency of this disease is unknown. The annual incidence has been estimated to be 0.4 to 0.5 in 100,000.[2] The risk for symptomatic *Nocardia* infection is greatly increased (estimated to be 140 to 340 times greater) in individuals who are immunocompromised, including patients who are receiving immunosuppressive agents following a stem cell[3] or solid organ transplant,[4] and patients with acquired immunodeficiency syndrome (AIDS). Corticosteroids are the most frequent immunosuppressant associated with nocardiosis, but cases also have been reported in patients who are receiving anti–tumor necrosis factor-α antibody agents as well as other immunosuppressants. Trimethoprim-sulfamethoxazole prophylaxis, as is used to prevent infections with *Pneumocystis jiroveci*, does not always protect against *Nocardia*. Other

306 NOCARDIOSIS

FREDERICK S. SOUTHWICK

DEFINITION

Nocardiosis refers to infections caused by *Nocardia* spp. *Nocardia* most commonly causes pneumonia but also can infect the central nervous system (CNS) and the skin. Less commonly, this organism can disseminate throughout the body. These infections usually occur in immunosuppressed patients.

The Pathogen

Nocardia spp are thin, aerobic, gram-positive bacilli that form branching filaments.[1] The bacteria stain irregularly and appear beaded on Gram stain and positive on modified acid-fast stain. The species are now identified by gene sequencing and DNA-DNA hybridization. The number of species causing human disease is large and includes *N. abscessus, N. brevicatena/paucivorans* complex, *N. nova* complex, *N. transvalensis* complex, *N. farcinica, N. cyriacigeorgica, N. otitidiscaviarum, N. veterana, N. brasiliensis*, and *N. pseudobrasiliensis*.

EPIDEMIOLOGY

Nocardia spp are ubiquitous and primarily originate in soil. Despite being found throughout the environment, they rarely cause symptomatic infection in humans. Because nocardiosis is not a reportable disease, the frequency of this disease is unknown. The annual incidence has been estimated to be 0.4 to 0.5 in 100,000.[2] The risk for symptomatic *Nocardia* infection is greatly increased (estimated to be 140 to 340 times greater) in individuals who are immunocompromised, including patients who are receiving immunosuppressive agents following a stem cell[3] or solid organ transplant,[4] and patients with acquired immunodeficiency syndrome (AIDS). Corticosteroids are the most frequent immunosuppressant associated with nocardiosis, but cases also have been reported in patients who are receiving anti–tumor necrosis factor-α antibody agents as well as other immunosuppressants. Trimethoprim-sulfamethoxazole prophylaxis, as is used to prevent infections with *Pneumocystis jiroveci*, does not always protect against *Nocardia*. Other

ABSTRACT

Nocardia species is a gram-positive and acid-fast filamentous aerobic bacteria found in the soil that infects humans primarily through *inhalation* of dust and, less commonly, secondary to cutaneous inoculation following trauma. This bacterium can cause nodular lung lesions and lymphocutaneous infections. When nocardia disseminates into the blood stream, it can result in multiloculated brain abscesses that can be identified by head CT scan with contrast. These infections are more common in immunocompromised patients. The organism is slow growing and takes several days to be identified. Speciation is now performed by polymerase chain reaction (PCR) testing, and certain strains, particularly *N. farcinica*, are trimethoprim-sulfa resistant; therefore, for serious infections combination therapy is recommended with ceftriaxone, imipenem, or amikacin. Linezolid and moxifloxacin have also been shown to be effective in some cases. In patients with brain abscess, surgical drainage in addition to long-term antibiotics is required. The recommended duration of therapy is 4 to 6 months for a normal host and 6 to 12 months for immunocompromised patients.

mycetoma

at-risk groups include patients with cancer, Cushing syndrome (Chapter 208), chronic granulomatous disease (Chapter 231), and hypogammaglobulinemia (Chapter 231). Patients with chronic pulmonary disorders, particularly alveolar proteinosis (Chapter 79), are also more susceptible to this infection.[5] In approximately one third of patients with nocardiosis, no predisposing condition can be identified.

PATHOBIOLOGY

Most *Nocardia* spp gain entry to the host via the respiratory tract or, less commonly, by skin inoculation. Invading bacteria elicit a neutrophilic response that inhibits but does not kill the organism. The bacteria are phagocytosed by neutrophils and macrophages and then become enclosed in a membrane-bound phagolysosome. In this closed environment, neutrophils and macrophages can kill many species of bacteria by synthesizing superoxide and hydrogen peroxide. However, *Nocardia* can survive by producing superoxide dismutase, an enzyme that inactivates these toxic oxygen byproducts. In addition, *Nocardia* spp produce a mycolic acid called cord factor that inhibits the fusion of lysosomes with the phagolysomal compartment, thereby preventing toxic proteases and other antibacterial products from reaching the intracellular bacteria. Cell wall extractable lipids impair phagocytosis and inhibit bacterial killing. In addition to neutrophils and macrophages, cell-mediated and humoral immunity also play roles in protecting the host against *Nocardia* invasion, thereby explaining the wide range of immunocompromised patients that are at increased risk for contracting nocardiosis.

CLINICAL MANIFESTATIONS

Nocardiosis has no pathognomonic characteristics. Failure of a pulmonary or skin infection to respond to conventional antibiotic therapy should raise the possibility of a *Nocardia* spp infection. *Nocardia* also can rarely cause bacteremia[6] and even endocarditis.[7] The symptoms and signs of nocardiosis are comparable in immunocompromised and nonimmunocompromised patients.

Pulmonary Nocardiosis

Approximately two thirds of patients with nocardiosis present with pulmonary infection.[8] Pulmonary disease is usually subacute in onset, similar to a fungal (Chapter 308) or mycobacterial infection (Chapters 299 and 300). The most common complaints are a persistent cough with purulent sputum, fever, anorexia, and weight loss. Less commonly, patients may report pleuritic chest pain and dyspnea. Hemoptysis is rare but can develop in patients with large cavitary lesions. Acute onset of pneumonia has occasionally been reported in the immunocompromised host.[9]

Central Nervous System Infection

Approximately 5% of patients with a *Nocardia* infection have CNS involvement, with multilocular brain abscess the most common manifestation,[10] usually the consequence of transient bacterial dissemination from the lung. Lesions can occur in any region of the brain, and symptoms depend on location. Headache is the usual initial complaint and is frequently localized to the site of the abscess. Patients also may present with neurologic deficits and seizures. Meningitis is a less common CNS manifestation and is often associated with brain abscess.

Cutaneous Infection

Skin infection is usually caused by *N. brasiliensis* and typically follows a break in the skin that is contaminated by soil. Cutaneous disease has been reported in association with trauma, a postoperative wound, insect bites, thorn bush scratches, or even a cat scratch. Initially, a pustule or a moderately erythematous, nonfluctuant nodule develops at the site of inoculation. Erythema can extend along the lymphatic system and is associated with tender lymphadenopathy.[11] This form of cutaneous infection has been termed *lymphocutaneous* or *sporotrichoid* disease. In the immunocompromised host, disseminated infection may be manifest by multiple erythematous raised nodules and is an ominous finding. In tropical regions of South and Central America, *Nocardia* spp can cause ulcerations and large tumor-like lesions called *mycetomas* that are usually found on the lower legs.

DIAGNOSIS

Delays in diagnosis are common because nocardiosis has no specific clinical manifestations. Pulmonary disease is most commonly misdiagnosed as tuberculosis.[12] The combined findings of a lung nodule on a chest radiograph and a ring-enhancing CNS lesion are often mistaken for metastatic lung carcinoma.

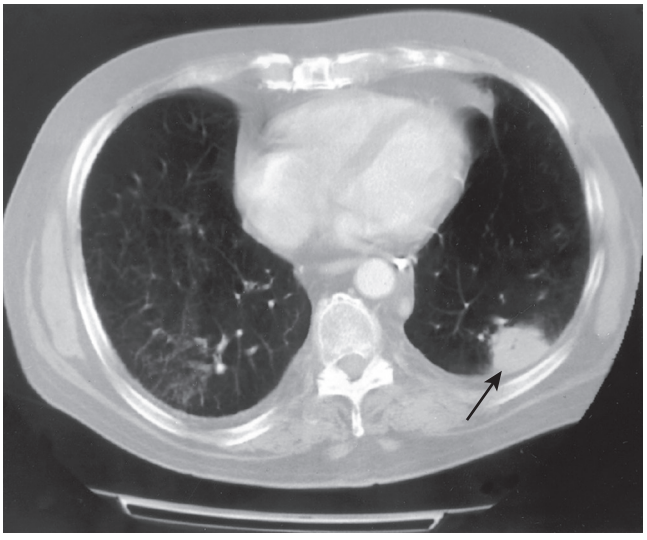

FIGURE 306-1. Chest computed tomography showing a peripheral nodular lung lesion (*arrow*) caused by *Nocardia* infection.

Other diagnoses that should be considered when an immunocompromised host presents with both a lung and CNS lesion are disseminated aspergillosis (Chapter 311) and toxoplasmosis (Chapter 320). Skin manifestations similar to *Nocardia* infection are seen with other etiologies, including cat scratch disease (Chapter 291), tularemia (Chapter 287), *Mycobacterium marinum* (Chapter 300), and sporotrichosis (Chapter 324).

Radiology

In pulmonary disease, chest radiographic findings are variable, with pulmonary nodules or mass lesions being seen most often (Fig. 306-1). Less frequently, consolidation, cavitary lesions with air-fluid levels, interstitial infiltrates, and pleural effusions are found. A chest computed tomographic (CT) scan often demonstrates areas of low attenuation within consolidations, multiple nodules, and chest wall extension of the infection. Patients with AIDS are more likely to have multiple pulmonary nodules, cavitary lesions, and upper lobe infiltrates. In some patients, the infiltrate may resolve, particularly in patients with normal immune function. However, the patient may present with brain abscess several months later because of transient bacteremia. In CNS infection CT or magnetic resonance imaging with contrast usually demonstrates one or more ring-enhancing lesions (Fig. 306-2). *Nocardia* brain abscess is more commonly multiloculated; otherwise, the radiologic findings are consistent with other bacterial brain abscesses (Chapter 382). Positron emission tomography is not helpful in differentiating *Nocardia* brain abscess from tumor because both demonstrate increased uptake.

Diagnostic Procedure

Polymerase chain reaction testing has been shown to be sensitive and specific for diagnosing *Nocardia* infections in research studies, but these tests are not usually commercially available. As a result, invasive procedures are generally required for specific diagnosis. For pulmonary infection, bronchoscopy with transbronchial biopsy or needle biopsy is recommended.

In nocardial meningitis, the cerebrospinal fluid (CSF) cell count usually reveals neutrophils, and the CSF culture may be positive, particularly if the culture is held for a prolonged period. CT-guided needle aspirate is the diagnostic procedure of choice for brain abscess. Histopathologic examination usually reveals an acute inflammatory response with a predominance of neutrophils.

Micronodular abscesses with minimal capsular formation are usually found. Gram stain or Brown-Brenn stains reveal gram-positive, beaded, branching forms. The morphology is identical to that of *Actinomyces* (Chapter 304), although the high lipid content of its cell wall often renders *Nocardia* modified acid-fast positive.

Bacteriology

Isolation of the organism on culture provides a definitive diagnosis from needle aspirate samples of brain abscess and a presumptive diagnosis when grown from respiratory and cutaneous samples. Because the organism needs 3 to 5 days to form colonies on blood agar, other organisms can overgrow. When *Nocardia* is suspected, the clinical laboratory should be notified to allow the use of selective

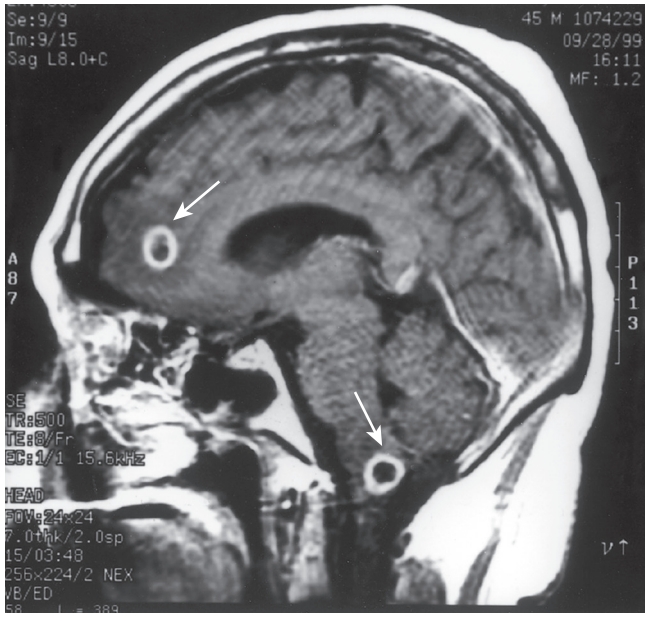

FIGURE 306-2. **Multiple gadolinium-enhanced brain lesions (*arrows*) caused by *Nocardia* infection.**

media and prolonged incubation.[13] RNA gene sequencing allows rapid speciation of isolates,[14] but its role in diagnosis is uncertain in pulmonary samples because it cannot differentiate true infection from colonization.[15] Antibiotic susceptibility testing always should be performed to guide the choice of therapy.[16]

TREATMENT

Because of the rarity of nocardiosis, no prospective treatment trials have been performed, and all recommendations are based on retrospective studies and in vitro sensitivity testing. For pulmonary and cutaneous infections, trimethoprim-sulfamethoxazole given orally at a dose of 160/800 mg (one double-strength tablet) three times daily is the most commonly used adult regimen.

For patients with disseminated and/or CNS infections, however, combination therapy is generally recommended,[17] with the exact regimen guided by antibiotic susceptibility testing. One recommended empirical regimen is trimethoprim-sulfamethoxazole (15 mg/kg/day IV of the trimethoprim component divided into two to four doses) and amikacin (7.5 mg/kg IV every 12 hours), plus either ceftriaxone (2 g IV twice daily) or imipenem (500 mg IV four times daily). Prolonged therapy with linezolid (600 mg twice daily) has been used successfully against nearly all strains of *Nocardia*,[18] and it can be used as monotherapy with CNS or disseminated disease or as a substitute for trimethoprim/sulfamethoxazole in multidrug regimens[19] with less toxicity than trimethoprim-sulfamethoxazole. However, because of its bone marrow toxicity, peripheral cell counts should be monitored weekly. Moxifloxacin (400 mg/day orally) has activity against several strains of *Nocardia*, including *N. farcinica* and *N. brasiliensis*, and can be useful in patients who cannot tolerate sulfonamides; however, relapse has been reported. Minocycline (100 mg orally twice daily) and amoxicillin-clavulanate (875/125 mg orally twice daily) are other potentially effective substitutes for trimethoprim-sulfamethoxazole as monotherapy or combined therapy for *Nocardia*. Because of the intracellular nature of *Nocardia* and its slow rate of growth, antibiotic treatment is usually required for 6 to 12 months to prevent relapse in the immunocompromised host and for 4 to 6 months in the normal host.[20] For patients with a brain abscess[21] or subcutaneous abscesses, surgical drainage as well as antibiotics are required for cure.

PROGNOSIS

The overall mortality for nocardiosis is approximately 25%. In otherwise healthy individuals, pulmonary nocardiosis has a better prognosis (15% mortality). The survival rate is worse in patients with bacteremia, patients with acute infection (symptoms for <3 weeks), patients receiving corticosteroids or cytotoxic agents, patients with disseminated disease involving two or more noncontiguous organs, and patients with meningitis.

SYSTEMIC ANTIFUNGAL AGENTS

DAVID W. DENNING AND DAVID A. STEVENS

Methods for in vitro testing of antifungal susceptibility are available as standardized tools. A variety of assays also are available for therapeutic monitoring of drug levels in the serum and other bodily fluids. The increasing prevalence of drug resistance requires careful antifungal stewardship programs.[1,2] Drug-drug interactions are a particular prescribing challenge for triazole antifungal agents.

AZOLE ANTIFUNGAL AGENTS

Mechanisms of Action

The azole ring confers antifungal activity on a variety of synthetic organic compounds. *N*-substitution of imidazoles has created a family of drugs called *triazoles* that have the same mechanism of action as imidazoles, a similar or broader spectrum of activity, and less effect on human sterol synthesis. Both imidazoles and triazoles inhibit C-14α demethylation of lanosterol in fungi; this leads to reduced concentrations of ergosterol, which is essential for a normal fungal cytoplasmic membrane. The principal pharmacodynamic driver for the response of *Candida* spp to the triazole antifungal agents has been the ratio of total drug exposure (area under the curve) to the minimum inhibitory concentration. For *Aspergillus* spp, the critical driver has been the amount of time that the drug is above a critical inhibitory threshold. Because of their interaction with the cytochrome P-450 (CYP) system and, in some cases, the P-glycoprotein pumps, the azoles as a class have a large number of drug-drug interactions, about 10% of which cause important clinical events.[3] Careful attention must be paid to these potential interactions whenever azoles are prescribed (see https://www.aspergillus.org.uk/antifungal-drug-interactions/).

Newer triazoles have properties that make them preferable to ketoconazole. These properties include not only less hormonal inhibition but also better distribution into body fluids, the availability of both parenteral and oral formulations, less hepatotoxicity, and a broader spectrum. Resistance to azoles is emerging in previously susceptible species, and new resistant species, such as *Candida auris*, have spread globally. Resistance mechanisms include increased drug efflux, as well as altered or increased C-14α demethylase. Some of the common resistance mutations seen in *Aspergillus* isolates from certain geographic areas may have arisen owing to the widespread agricultural use of azole fungicides. All agents in this class have the potential for embryotoxicity and teratogenicity, so they generally should be avoided during pregnancy, particularly during the first trimester.

ITRACONAZOLE

Formulations and Pharmacology

Itraconazole is marketed as a capsule, as a new super bioavailable (SUBA)-itraconazole capsule with better bioavailability, and as an oral and intravenous suspension in cyclodextrin (an oligosaccharide ring). The ring entraps the hydrophobic, water-insoluble drug, thereby making it soluble. Oral absorption of the capsule is significantly enhanced by food, whereas absorption of the oral solution is best on an empty stomach. By comparison, absorption of SUBA-itraconazole does not vary with food. Peak levels with oral preparations are achieved 4 to 6 hours after a dose. Steady state is achieved only after 13 to 15 days, at which time the β-elimination half-life is approximately 19 to 22 hours. Absorption of the capsule is markedly depressed in patients who have graft-versus-host mucositis and in patients who have enteritis caused by acquired immunodeficiency syndrome (AIDS), but this problem can be alleviated by using the solution or SUBA-itraconazole.

Bioassays of itraconazole yield much higher concentrations than by direct measurement because of the hydroxyitraconazole metabolite. Hydroxyitraconazole, which appears in the blood in amounts roughly twice that of the parent drug, has antifungal activity and pharmacokinetics similar to those of the parent compound. Concentrations of itraconazole in tissue, pus, and bronchial secretions are generally higher than those in plasma. Ocular levels are low. Saliva concentrations persist for 8 hours after administration of the solution and may be beneficial in treating oral disease or eradicating oral colonization. The drug is metabolized in the liver (so its half-life is prolonged in patients with cirrhosis) and excreted in feces as metabolites. No useful

The drug is metabolized in the liver (so its half-life is prolonged in patients with cirrhosis) and excreted in feces as metabolites. No useful

ABSTRACT

Advances in medicine have increased the incidence and prevalence of mycoses but also have improved the availability of effective antifungal therapies. The clinician now has a choice among several classes of drugs, each with a different mechanism of action. Clinicians should be familiar with the indications and risks for these agents so as to choose what is best for their patients. The in vitro susceptibility of the patient's pathogen and therapeutic drug monitoring in body fluids assist the clinician in selecting therapy, monitoring its efficacy, and avoiding side effects. Nevertheless, the emergence of resistance to these available drugs and the emergence of new, resistant fungal species pose an ongoing challenge.

amount of bioactive itraconazole appears in urine. Plasma concentrations do not increase in patients with renal insufficiency or decrease with hemodialysis.

Indications and Dosage

Itraconazole is useful for the treatment of invasive aspergillosis (Chapter 311), allergic bronchopulmonary aspergillosis,[A1] chronic pulmonary aspergillosis,[4] blastomycosis (Chapter 308), histoplasmosis (Chapter 308), meningeal and nonmeningeal coccidioidomycosis (Chapter 308), paracoccidioidomycosis (Chapter 308), sporotrichosis (Chapter 308), talaromycosis, phaeohyphomycosis (Chapter 314), mucosal candidiasis (Chapter 310), ringworm (including terbinafine-resistant infections),[A2] and tinea versicolor (Chapter 405). Itraconazole is also useful for the prevention of relapse of disseminated histoplasmosis in patients with AIDS. SUBA-itraconazole or oral solution can be used for antifungal prophylaxis in immunosuppressed and neutropenic patients, and intravenous itraconazole can be used as empiric therapy for episodes of febrile neutropenia (Chapter 260).

For deep mycoses, an initial oral itraconazole dose of 200 mg three times daily is recommended for the first 3 days to achieve high serum and tissue levels quickly (Table 307-1). SUBA-itraconazole requires only 100 mg twice daily. For intravenous use, a 200 mg loading dose four times daily is then followed by 200 mg twice daily.

Drug Interactions

Drugs that decrease gastric acidity reduce the absorption of capsules, except for SUBA-itraconazole. Some of the most notable drug interactions are rifampin, rifabutin, isoniazid, phenytoin, and carbamazepine, all of which decrease itraconazole blood levels. Itraconazole decreases rifampin blood levels and increases blood levels of some antihistamines and ivabradine, thereby potentially causing ventricular tachycardia. It also increases blood levels of warfarin, benzodiazepines, statins, dihydropyridine calcium-channel blockers, digoxin, quinidine, cyclosporine, tacrolimus, methylprednisolone, human immunodeficiency virus (HIV) protease inhibitors (e.g., ritonavir, indinavir, elvitegravir/cobicistat), and vinca alkaloids.

Adverse Effects

The most common adverse effect is dose-related nausea and abdominal discomfort, but symptoms rarely necessitate stopping therapy. Dividing the dose and administering the drug twice daily can improve tolerance and raise blood levels. Hypokalemia and edema may occur at doses of 400 mg/day or higher. Allergic rash is seen occasionally. Itraconazole is rarely hepatotoxic. Diarrhea, nausea, and other gastrointestinal complaints are more frequent with the oral solution. A negative inotropic effect, which is manifested as subacute onset of heart failure, is rarely seen. Longer-term use can result in peripheral neuropathy. Itraconazole during pregnancy is associated with increased fetal loss.

FLUCONAZOLE

Formulations and Pharmacology

Fluconazole is currently available in oral and vaginal tablets, as a powder for oral suspension, and as an intravenous formulation. Fluconazole is well absorbed from the gastrointestinal tract. Of the oral dose, 60 to 75% appears unchanged in the urine. Fluconazole penetrates into the brain, cerebrospinal fluid (CSF), saliva, sputum, and urine.

Fluconazole's half-life increases with diminished renal function. Although the dose may be reduced in such circumstances, the drug's toxicity is minimal even at high exposures, so the tendency to reduce the dose must be weighed against the risk of undertreatment. The dose should be doubled in patients who are receiving hemofiltration because of rapid clearance. Patients receiving hemodialysis should have one daily dose after each session.

Indications and Dosage

Candidiasis (Chapter 310)

Provided the infection is not caused by fluconazole-resistant *Candida*, fluconazole (see Table 307-1) is effective for the treatment of oropharyngeal and esophageal candidiasis. A single dose of 150 mg is as effective for vulvovaginal candidiasis. For candidemia or deep-seated candidiasis in immunosuppressed patients or for rapidly progressing or severely ill patients, especially in initial therapy before susceptibilities are known, an echinocandin or an amphotericin preparation is preferred. Fluconazole can be useful for prophylaxis (in some immunocompromised patients, with intra-abdominal surgery, and in severe pancreatitis) and as oral continuation therapy at hospital discharge. Use of this drug for prophylaxis may, however, result in shifts to less susceptible species in patient flora. In patients with *Candida* endocarditis (Chapter 61), long-term fluconazole therapy has been used to prevent relapse.

Cryptococcal Meningitis (Chapter 309)

Initial fluconazole is not as good as amphotericin B combined with flucytosine as therapy for cryptococcal meningitis.[A3] High-dose fluconazole is often given with these two agents in initial therapy, and it may be combined with flucytosine for dual therapy in patients who are not HIV-infected.[5] Continuation therapy with oral fluconazole 400 mg/day for 2 months is commonly used if the patient is clinically stable, followed by 200 mg/day at least until antiretroviral therapy results in a substantial rise in the CD4 count. Resistance to fluconazole is an increasing concern. Fluconazole is effective for the eradication

of genitourinary foci. For patients without AIDS, fluconazole is useful for patients who have completed a course of amphotericin B and are at high risk for relapse. It is effective for primary prophylaxis but is rarely used for this purpose.

Other Mycoses

Fluconazole is useful for coccidioidomycosis, especially meningitis, soft tissue infections, and pulmonary infections (Chapter 308), but itraconazole is commonly preferred for skeletal infections owing to its superior efficacy. For cutaneous sporotrichosis, ringworm, histoplasmosis, and blastomycosis, itraconazole is superior to fluconazole.

Drug Interactions

Among other drug interactions, fluconazole can cause significant increases in the blood level of phenytoin, glipizide, glyburide, tolbutamide, warfarin, rifabutin, cisapride, quinidine, bosentan, and cyclosporine. Rifampin lowers fluconazole blood levels by approximately 25%.

Adverse Effects

Adverse effects are uncommon. Even with chronic therapy, including doses exceeding 400 mg/day, headache, usually reversible alopecia, and anorexia are the most common symptoms; about 10% of patients develop elevated aspartate aminotransferase levels. Toxicity is, however, increased with doses over 1200 mg/day. Fluconazole use during pregnancy increases cardiac defects at birth by about three-fold.

VORICONAZOLE

Formulations and Pharmacology

Voriconazole is marketed as tablets, an oral solution, topical eye drops, and a solution in sulfobutyl ether β-cyclodextrin for intravenous administration. Voriconazole is cleared by hepatic metabolism, with less than 2% of the dose excreted unchanged in the urine. Voriconazole exhibits nonlinear pharmacokinetics in adults, owing to saturation of the clearance pathways at higher doses, but linear kinetics in children, who usually clear the drug rapidly. The principal enzymes involved in clearance are hepatic CYP2C19 and CYP3A4. Despite significant genetic polymorphisms that affect the drug's metabolism, achieved plasma levels overlap, and an initial dose adjustment based on genotype or racial group is not necessary. Therapeutic drug monitoring with dose adjustments as necessary is recommended because favorable outcomes correlate with serum concentrations greater than 1 to 2 μg/mL, but neurologic/psychiatric, hepatic, or cardiac side effects occur with levels greater than 5 μg/mL.

Standard loading doses followed by maintenance doses that are 50% of normal are recommended for patients who are older than 75 years or have mild-to-moderate hepatic cirrhosis. Dosage adjustments are not required for renal dysfunction, and voriconazole is not significantly cleared by hemodialysis.

Indications and Dosage

The standard dosing of voriconazole in adults is 6 mg/kg intravenously and 200 to 300 mg orally, both twice daily, preceded by loading doses for 1 day in severely ill patients (see Table 307-1). Doses should be adjusted by therapeutic drug monitoring, and lower doses such as 150 mg twice daily are preferred in older (age >75 years) and low weight (<50 kg) patients. Treatment is given for weeks or months.

Aspergillosis (Chapter 311)

Voriconazole is superior to amphotericin B for the treatment of invasive aspergillosis, in which it increases the likelihood of a successful outcome from about 30% to about 50%. Voriconazole is also recommended for chronic pulmonary aspergillosis.

Other Mycoses

Voriconazole also is effective for the treatment of invasive fusariosis and scedosporiosis.[6] Infections by *Scedosporium apiospermum* complex may respond, but *Lomentospora (Scedosporium) prolificans* infections are commonly resistant. The drug is efficacious in esophageal candidiasis (Chapter 124), invasive candidiasis (Chapter 310), refractory candidiasis, chronic pulmonary aspergillosis (Chapter 311), and allergic bronchopulmonary aspergillosis.[A4] It is useful for prophylaxis (in doses similar to what are used therapeutically) during periods of highest risk in high-risk allogeneic hematopoietic cell transplant recipients (Chapter 163) and in patients with severe aplastic anemia,[A5] but breakthrough mucormycosis can occur.

Drug Interactions

Voriconazole has many drug interactions. Rifampin, carbamazepine, long-acting barbiturates, glucocorticoids, and ritonavir induce the hepatic enzymes responsible for the clearance of voriconazole and thereby reduce voriconazole levels. Sirolimus levels are increased dramatically. Prolonged sedation is likely if voriconazole is coadministered with methadone, hydrocodone, alfentanil, fentanyl, or other short-acting opiates. Reduction in the clearance of pimozide, quinidine, ivabradine, and some antihistamines increases the risk for QT prolongation. Coadministration should be avoided with naloxegol, everolimus, St. John's wort, and venetoclax. Cyclosporine, tacrolimus, warfarin, statins, benzodiazepines, calcium-channel blockers, sulfonylureas, and vinca alkaloids can be coadministered, but the dosages of these drugs may need to be reduced, and clinical or laboratory monitoring is suggested. Coadministration of voriconazole with omeprazole or elvitegravir-cobicistat elevates the levels of both drugs. Voriconazole with rifabutin, phenytoin, or efavirenz results in lower voriconazole levels and elevated levels of the other drug. Numerous other interactions have been documented, and any cytochrome P-450 inhibitors, blockers, or inducers could have an interaction with voriconazole.

Adverse Effects

Transient, reversible visual disturbance beginning approximately 30 minutes after a dose is common. Hallucinations, unsteadiness, confusion, and liver enzyme abnormalities also have been associated with higher blood levels. Photosensitivity can be severe and has been associated with skin cancers in rare instances. Prolongation of the QT interval and tachyarrhythmias have been noted in patients with pro-arrhythmic risk factors, such as electrolyte abnormalities. Periostitis has been noted after prolonged therapy, apparently related to the fluoride atoms in the molecule. Leukoencephalopathy has been rarely reported.

POSACONAZOLE

Formulations and Pharmacology

Posaconazole is available as an oral suspension, as tablets, and as an intravenous form admixed with sulfobutyl ether β-cyclodextrin. Absorption of the tablet is superior to the suspension. The half-life is 20 to 35 hours. Clearance is primarily by fecal excretion, with only 13% excreted via renal clearance. Hepatic metabolism via uridine diphosphate glucuronidation plays only a small role in clearance, and CYP-mediated oxidation does not occur. The drug is concentrated in phagocytes.

Indications and Dosage

Posaconazole has a very broad spectrum of activity against molds, including many Mucorales,[7] and the least cross-reactivity among the azoles to resistance-causing mutations in the ergosterol synthesis pathway. It is effective in preventing opportunistic mycoses in transplant patients with graft-versus-host disease (Chapter 163) and in patients with hematologic malignancies and neutropenia.[A6] Intravenous posaconazole is equivalent to isavuconazole for invasive aspergillosis (Chapter 311),[A7] and it also is effective for chronic pulmonary aspergillosis (Chapter 311), coccidioidomycosis (Chapter 308), mucormycosis (Chapter 312),[8] and superficial candidiasis (Chapter 310).

The dose is 300 mg/day twice daily orally or intravenously on the first day, then 300 mg/day for treatment of deep-seated mycoses and for prophylaxis, whereas 100 to 200 mg oral solution has been used for mucosal candidiasis (see Table 307-1). Duration of therapy, which is dependent on the indication, can be many weeks or months for deep-seated mycoses. At steady state, 300 mg/day of tablet or intravenous preparation yields concentrations of about 1.4 μg/mL. Therapeutic drug monitoring is advisable in patients who are taking the solution and in patients who are taking tablets while also on proton pump inhibitors. Levels greater than 0.7 μg/mL correlate with efficacy in prophylaxis. Dosage adjustment is not needed for hepatic or renal failure or hemodialysis.

Drug Interactions

Although posaconazole has fewer interactions than itraconazole and voriconazole, significant interactions include increased levels of calcium-channel blockers, cyclosporine, sirolimus, tacrolimus, quinidine, ivabradine, atazanavir, amiodarone, cisapride, corticosteroids, digoxin, benzodiazepines, methylprednisolone, venetoclax, and drugs used for erectile dysfunction. Posaconazole levels may be increased by cobicistat. Posaconazole levels are reduced by cimetidine, efavirenz, metoclopramide, rifampin, and, in some studies, with diarrhea and proton pump inhibitors. Posaconazole with phenytoin, carbamazepine, or rifabutin results in lower posaconazole levels and elevated levels of the other drug.

Adverse Effects

Gastrointestinal symptoms, headache, acneiform rashes of the face, and abnormal liver function are occasionally seen. Electrolyte abnormalities should be rectified before therapy to avoid electrophysiologic effects, which manifest clinically as arrhythmias. A unique effect in up to 25% of patients is pseudohyperaldosteronism syndrome, which presents with hypokalemia and hypertension. The mechanism appears to be inhibition of the 11-β-hydroxylase enzyme, thereby resulting in an accumulation of aldosterone precursors, particularly 11-deoxycorticosterone, with effects on the mineralocorticoid receptor resulting in potassium excretion and hypertension. A second effect is inhibition of 11-β-hydroxysteroid dehydrogenase type 2, resulting in accumulation of cortisol, which also activates the mineralocorticoid receptor. This syndrome is more common in older patients, patients with a higher baseline blood pressure, and patients with higher blood drug levels. Rarely, glucocorticoid deficiency has been seen in these patients.

ISAVUCONAZOLE

Formulations and Pharmacology

Isavuconazonium is a water-soluble prodrug cleaved virtually completely by plasma esterases to form isavuconazole. Isavuconazonium is available for oral or intravenous use.[9] The pharmacokinetics are linear. The drug is highly protein bound. After oral administration, peak levels are reached in 2 to 3 hours, with a very long half-life of 60 to 130 hours. If given intravenously, the bottle should not be shaken to avoid precipitation. Switching at any time from intravenous to oral dosing is facilitated by the fact that the pharmacokinetics are unchanged. The pharmacology is unaffected by meals, renal impairment, or the patient's age, race, or gender. Hepatic insufficiency produces small pharmacologic changes, and no dose alteration is recommended.

Indications and Dosage

The enthusiasm for this drug relates directly to its activity in patients with mucormycosis (Chapter 312)[A8] and aspergillosis (Chapter 311).[A9] The antifungal activity in vitro is broad, the biggest exceptions being *Aspergillus niger*, *Fusarium*, and *Wangiella* species. Activity against species of Mucorales is broad and probably less variable than posaconazole. In small series of patients, activity appears promising against cryptococcosis, paracoccidioidomycosis, coccidioidomycosis, histoplasmosis, and blastomycosis. However, it appears to be inferior to caspofungin for the treatment of candidemia and invasive candidiasis (Chapter 310). The recommended dosing is to load with 372 mg (equivalent to 200 mg isavuconazole) three times daily for 2 days, then switch to once daily for weeks or months, depending on the clinical indication, degree of immunosuppression, response to therapy, and tolerance (see Table 307-1).

Drug Interactions

Although there are interactions with hepatic CYP 3A4 enzymes, the frequency of drug interactions is lower than with other triazoles. Undetectable isavuconazole concentrations are seen with rifampin and probably rifabutin because of induction of CYP3A4. Methotrexate, efavirenz, and lopinavir/ritonavir levels are increased. Drug dosage adjustments and monitoring may be required for cyclosporine, tacrolimus, sirolimus, mycophenolate, midazolam, bupropion, bosentan, etravine, and digoxin.

Adverse Effects

QT intervals are shortened, and the drug is contraindicated in patients with familial short QT intervals. Common side effects include nausea (26%), vomiting (25%), and diarrhea (22%), with headache, hypokalemia, dyspnea, cough, and edema noted in 10 to 20% of patients. The overall frequency of serious side effects appears to be less than for voriconazole.

AMPHOTERICIN PREPARATIONS

Mechanism of Action

Amphotericin B is a lipophilic molecule that may exert its antifungal effect by inserting itself into the fungal cytoplasmic membrane and causing an increase in membrane permeability or may act by adsorption of ergosterol at the surface of the fungal cell membrane. The resulting loss of intracellular molecules impairs fungal viability. The onset of action is rapid. The antifungal activity of amphotericin B also may be enhanced by its effects on oxidation.

Formulations and Pharmacology

Conventional amphotericin B is formulated in deoxycholate and as multiple lipid-associated formulations, including liposomal amphotericin B. Although lipid-associated preparations usually carry less toxicity, larger doses (usually about three-fold) are required for the same level of efficacy. The precise lipid formulation affects the tissue distribution,[10] the circulating pharmacokinetics, and the toxicity profile of each preparation, so they are not identical or even equivalent. When compared on a milligram-per-kilogram basis, lipid-associated formulations produce tissue concentrations that range from 90% lower to 500% higher than seen with conventional amphotericin B, with the most consistent relative reduction seen in the kidney. Liposomal amphotericin B penetrates brain tissue at a higher concentration than conventional amphotericin. Liposomal amphotericin B, which has the least toxicity, has been used more extensively than other lipid-associated preparations.

All formulations of amphotericin B must be infused in 5% dextrose with no electrolytes added. Infusion bottles need not be protected from light. Based on years of experience, the deoxycholate preparation of amphotericin B tends to be used for topical, intravitreal, intrathecal, and oral infections.

Liposomal amphotericin B is formulated as small bilayer liposomes (<100 nm) containing cholesterol, hydrogenated soy phosphatidylcholine, and distearoylphosphatidylglycerol. These components ensure that the amphotericin B remains associated with the liposome, with high concentrations in blood, reticuloendothelial tissue, and brain but lower concentrations in the kidney and lung. Liposomes bind to fungal cell walls and then pass through it to allow amphotericin B to intercalate with ergosterol in the fungal cell membrane. Once the liposomes penetrate into tissues, amphotericin may be released into the circulation, where it appears to bind to host lipids. Penetration into activated vascular endothelium at sites of infection likely contributes to its efficacy. Given the retention of amphotericin B in circulating liposomes, there is uncertainty about release into vegetations on heart valves. Penetration of amphotericin B into the eye, urine, pleural, bronchial, peritoneal fluid, synovial fluid, and cerebrospinal fluid is low and likely to be even lower with liposomal amphotericin B.

Indications and Dosage

Amphotericin B is active against most fungi, and its spectrum of activity is not influenced by the choice of formulation. Amphotericin B is infused intravenously over a 2- to 4-hour interval. More rapid infusion in patients with severely compromised renal function may lead to acute, marked hyperkalemia and ventricular fibrillation.

When resistance occurs, it is generally attributed to reductions in the biosynthesis of ergosterol and the synthesis of alternative sterols that lessen the ability of amphotericin B to interact with the fungal membrane; oxidant scavengers also may be produced. Primary resistance is common for *Aspergillus terreus* and *Aspergillus nidulans*, *Scedosporium*, *Lomentospora*, and *Trichosporon* species. Among the *Candida* species, primary resistance is noted at meaningful frequencies most often for *Candida lusitaniae* and sometimes for *Candida auris*. Development of resistance in isolates of normally susceptible species is rare. The principal pharmacodynamic driver of in vivo response is likely the ratio of the peak serum concentration to the minimum inhibitory concentration.

Intravenous liposomal amphotericin B at a dose of 3 mg/kg daily is appropriate for almost all indications, typically for 1 to 6 weeks (see Table 307-1). It is the antifungal agent of first choice for disseminated histoplasmosis, talaromycosis, cryptococcal meningitis, and mucormycosis. It is also effective for invasive candidiasis, but echinocandins are preferred. It is a second choice for invasive aspergillosis, unless azole resistance is demonstrated. Higher doses lead to greater toxicity without any clear therapeutic benefit, although a dose as high as 5 mg/kg is usually recommended for mucormycosis (Chapter 312). In visceral leishmaniasis (Chapter 319), a single dose of 40 mg/kg is effective, but 30 mg/kg combined with miltefosine is better. For cryptococcal meningitis in advanced HIV disease, a single dose of 10 mg/kg combined with flucytosine is effective.[A10] Lower daily doses have been used for prophylaxis in neutropenic hematology patients under the guidance of expert consultants.

Local instillation of amphotericin B into cerebrospinal fluid, joints, or pleura is rarely indicated. Fungal endophthalmitis (Chapter 391) is often treated with a single intravitreal dose of 5 to 10 μg conventional amphotericin. Coccidioidal meningitis (Chapter 308) may be treated with intrathecal amphotericin because it may produce superior results to systemic azole therapy, particularly in the long term, although with far greater toxicity.

Drug Interactions

The azotemia caused by amphotericin B is often worse in patients who are taking other nephrotoxic drugs but is not impacted by the use of intravenous radiographic contrast material. Renal dysfunction caused by amphotericin B can result in flucytosine toxicity. In patients with leishmaniasis (Chapter 319), the combination of amphotericin B and sodium stibogluconate should be avoided.

Adverse Effects

Amphotericin B can rarely cause anaphylaxis. In patients with a history of reaction to amphotericin B, a test dose of 1 mg (or 10 mg if liposomal amphotericin B) should be given over 15 minutes with subsequent observation.

Chills, fever, and tachypnea occur in some patients during infusion with liposomal amphotericin B but are much more common with conventional amphotericin. Slowing the infusion rate helps. Such reactions should not be mistaken for anaphylaxis or considered a contraindication to further use of amphotericin B. A patient with underlying cardiac or pulmonary disease may develop hypoxemia. These infusion-related reactions are less common in patients who are receiving corticosteroids. Milder reactions are usual with subsequent daily dosing. Premedication with acetaminophen is helpful. Patients with rapidly progressive mycoses should receive a full therapeutic dose within 24 hours.

Amphotericin B causes a dose-dependent decrease in the glomerular filtration rate because of a direct vasoconstrictive effect on afferent renal arterioles that reduces glomerular and renal tubular blood flow. Other effects on the kidney include potassium, magnesium, and bicarbonate wasting, as well as decreased erythropoietin production. Loss of renal function is due to the destruction of renal tubular cells, disruption of the tubular basement membrane, and loss of functioning nephron units. All of these toxicities are substantially reduced, but not eliminated, with liposomal amphotericin B. The serum creatinine level should be measured daily in the first few days of therapy and then at least twice weekly. Saline loading, such as the infusion of 1 L saline before infusion, may reduce nephrotoxicity. Potassium and magnesium wasting, which may be ameliorated with daily amiloride, often requires supplementation of these electrolytes. Curtailing of amphotericin B therapy is appropriate if the creatinine clearance falls by 40 to 50%, but longer courses of liposomal amphotericin B result in some permanent loss of renal function in about 15% of patients.

Administration via a peripheral cannula rather than a central line is possible with liposomal amphotericin B but not conventional amphotericin, because of phlebitis. Nausea, anorexia, and vomiting are common but much milder with liposomal amphotericin B than with conventional amphotericin. Bone pain, which is an uncommon but particular feature of liposomal amphotericin B, can be severe. Normocytic normochromic anemia occurs gradually, but the hematocrit rarely falls below 20 to 25% unless other causes of anemia are present. Rarely, thrombocytopenia, modest leukopenia, elevated transaminase levels, arrhythmias, coagulopathy, hemorrhagic enteritis, tinnitus, vertigo, encephalopathy, seizures, hemolysis, reticular rash, nephrogenic diabetes insipidus, or dysesthesia of the soles of the feet may be observed.

Amphotericin B and its lipid derivatives appear to be safe during pregnancy.

ECHINOCANDIN ANTIFUNGAL AGENTS

Mechanisms of Action

The echinocandin antifungal agents act by inhibiting the synthesis of 1,3-β-D-glucan in the fungal cell wall. The principal pharmacodynamic driver of in vivo response is the ratio of the peak concentration to the minimum inhibitory concentration. The three currently licensed echinocandins are caspofungin, micafungin, and anidulafungin; another agent with a very long half-life, thereby allowing once-weekly administration, is in late-stage clinical development. These agents are similar to one another, with very few drug interactions, an admirably low adverse event rate (except they are contraindicated during pregnancy), and essentially identical antifungal spectra. Of the three drugs, caspofungin has the broadest array of approved indications and the most clinical data. All are cyclic lipopeptides that must be given intravenously.

The echinocandins are fungicidal against all *Candida* species, including isolates resistant to other agents, although they have reduced activity against isolates of *C. parapsilosis*, *C. guilliermondii*, and *C. famata*. Resistance, though uncommon, has increasingly been noted, especially in *C. auris* and *C. glabrata*, and it sometimes develops during therapy. All the agents are active against *Aspergillus* species, but activity is limited to growing and dividing hyphal elements, so they are fungistatic, and occasional resistant isolates have been described. Their activity against other fungi is limited.

CASPOFUNGIN

Formulations and Pharmacology

The clearance of caspofungin is through a combination of spontaneous chemical degradation, hydrolysis, and *N*-acetylation. Dose adjustments are not required for impaired renal function or hemodialysis. The clearance of caspofungin is modestly reduced in patients with moderate hepatic insufficiency, in whom dose reduction is recommended. Penetration into infected tissues appears to be good.

Indications and Dosage

Caspofungin is indicated for the treatment of invasive candidiasis (Chapter 310), where it appears to be superior to isavuconazole,[A11] and esophageal candidiasis (Chapter 124). Caspofungin is also indicated for invasive aspergillosis (Chapter 310) in patients who are refractory to or intolerant of other therapies. Because of its activity against these two major opportunistic pathogens, caspofungin is useful for empiric therapy in neutropenic patients, such as patients undergoing treatment for acute leukemia.[A12] The usual dose is 50 mg once daily (see Table 307-1), but doses greater than 70 mg daily appear to be well-tolerated. Treatment is typically given for 2 to 4 weeks, occasionally longer.

Drug Interactions

Caspofungin has few meaningful drug interactions. Cyclosporine coadministration increases blood caspofungin levels, probably due to reduced hepatic uptake of caspofungin and has been associated with increased hepatic aminotransferase levels, so concomitant use requires caution. Caspofungin reduces tacrolimus levels by approximately 20%, and dosage adjustments may be required. Rifampin reduces caspofungin blood levels by approximately 30%, so the daily dosage of caspofungin should be increased from 50 to 70 mg if these drugs are coadministered. Likewise, limited data on other inducers of drug clearance (efavirenz, nevirapine, phenytoin, dexamethasone, carbamazepine) suggest that reduced caspofungin levels are possible and that increasing the daily dose to 70 mg should be considered.

Adverse Effects

Adverse reactions with caspofungin are infrequent and minor. Phlebitis and symptoms possibly related to histamine release during rapid infusion have been reported. Occasional episodes of confusion are noted.

MICAFUNGIN

Micafungin has an in vitro spectrum and properties similar to those of caspofungin.

Formulations and Pharmacology

The drug is light sensitive. After an intravenous infusion, the terminal half-life is approximately 15 hours. Metabolism appears to be mostly through fecal excretion, with less than 1% excreted in the urine. The drug penetrates particularly well into the lungs, liver, kidneys, and gastric mucosa. No adjustment for hepatic or renal insufficiency is needed.

Indications and Dosage

Efficacy for invasive candidiasis (Chapter 310) and *Candida* esophagitis (Chapter 124) is similar to that of amphotericin or caspofungin. The recommended dose is 100 to 150 mg/day for 10 to 14 days (see Table 307-1). Once-daily dosing produces steady state in 3 days. For prophylaxis in neutropenic patients being treated for acute leukemia or myelodysplastic syndrome or in patients undergoing hematopoietic cell transplantation, 50 mg/day is efficacious.[A13] Limited experience suggests activity comparable to caspofungin against invasive aspergillosis (Chapter 311) and modest efficacy in chronic pulmonary aspergillosis.

Drug Interactions

Micafungin has fewer drug interactions than caspofungin. There is no interaction with cyclosporine or rifampin, but slight increases in blood levels of sirolimus, nifedipine, itraconazole, and amphotericin B have been noted.

Adverse Effects

Micafungin has an excellent safety profile. Histamine release, manifested most prominently by total body erythema, can be avoided by slow infusion. Phlebitis has been reported.

ANIDULAFUNGIN

Formulations and Pharmacology

Anidulafungin is slowly degraded by the chemical opening of its ring structure. A 100-mg dose produces a C_{max} (peak concentration achieved) of 8.6 μg/mL at a time of peak concentration (T_{max}) of 6 to 7 hours. The half-life is 30 to 50 hours. Dose adjustments are not required for renal or hepatic insufficiency.

Indications and Dosage

A single loading dose of 200 mg (3 mg/kg) should be given on day one followed by 100 mg (1.5 mg/kg) daily thereafter for 10 to 14 days (see Table 307-1), occasionally longer. Anidulafungin is indicated for the treatment of

invasive candidiasis (Chapter 310) and esophageal candidiasis (Chapter 124), where it is at least as efficacious as fluconazole. Its efficacy against *Candida parapsilosis* is least certain.

Drug Interactions

Anidulafungin has no meaningful CYP enzyme interactions. As a result, it is the best echinocandin to use in the presence of liver failure.

Adverse Effects

Histamine-mediated symptoms (e.g., rash, urticaria, flushing, pruritus, dyspnea, hypotension) have been noted on occasion, as has anaphylaxis, but they are infrequent when the rate of infusion does not exceed 1.1 mg/minute. Other adverse reactions to anidulafungin have generally been infrequent and minor (diarrhea, hypokalemia, elevated liver function tests, neutropenia, nausea, headache, dermatitis). Patients with hereditary fructose intolerance should not be given anidulafungin.

FLUCYTOSINE

Formulation and Pharmacology

Flucytosine (5-fluorocytosine) is the fluorine analog of a normal body constituent, cytosine. Flucytosine is marketed as 250- and 500-mg capsules and, in a few countries, as an intravenous formulation. Absorption from the gastrointestinal tract is rapid and complete, with approximately 90% of the dose excreted unchanged in the urine. Cerebrospinal fluid concentrations are approximately 75% of simultaneous serum concentrations. The drug also penetrates well into aqueous humor, joints, bronchial secretions, peritoneal fluid, brain, bile, and bone, and it is readily cleared by hemodialysis and peritoneal dialysis.

The half-life of the drug in the serum of patients with normal renal function is 3 to 5 hours. Abnormal hepatic function has no influence on its half-life, but decreased renal function prolongs the half-life.

Mechanisms of Action

Isolates of *Candida* species are usually susceptible, as are most isolates of *Cryptococcus* spp, as well as the melanin-pigmented molds that cause chromoblastomycosis. Flucytosine is not active against isolates of *Aspergillus* species at pH 7.4. Flucytosine interferes with DNA synthesis by its conversion to 5-fluouridine triphosphate, which, when incorporated into RNA, causes aberrant transcription. The principal pharmacodynamic driver of response is the proportion of time the blood level exceeds the minimum inhibitory concentration. Resistance may be due to loss of the cytosine permease that permits flucytosine to cross the fungal cell membrane or loss of any of the enzymes that lead to its conversion into forms that interfere with DNA or RNA synthesis.

Indications and Dosage

For cryptococcal meningitis, where flucytosine contributes to increased survival when given with amphotericin B or fluconazole, the most studied dose is 100 mg/kg/day in four divided doses, usually for 14 days (see Table 307-1). As an approximation, the total daily dose should be reduced to 75 mg/kg with a creatinine clearance of 26 to 50 mL/minute and to 37 mg/kg when the creatinine clearance is 13 to 25 mL/minute. Ideally, the blood level should be measured in azotemic patients 2 hours after the last dose and immediately before the next dose. These values should range between 10 and 100 µg/mL. Patients requiring hemodialysis can be given a single post-dialysis dose of 37.5 mg/kg. Further doses are adjusted by blood level.

Drug Interactions

Flucytosine is used in combination with other agents for candidiasis, such as infection in sanctuary sites (eye, brain, heart valve, urine), for multiresistant organisms, and in chromoblastomycosis at the same dose as for cryptococcal meningitis. Monotherapy is rarely used because primary drug resistance is not uncommon in *Candida* infection, and secondary drug resistance is common in cryptococcosis and chromoblastomycosis.

Adverse Effects

Flucytosine may cause nausea, rash, diarrhea, and hepatic dysfunction but is generally well tolerated. In the presence of azotemia (such as that caused by concomitant administration of amphotericin B), leukopenia, thrombocytopenia, and enterocolitis may appear. These complications seem to be far more frequent among patients whose flucytosine blood levels exceed 100 to 125 µg/mL. Patients whose renal function is changing while receiving flucytosine should have their serum flucytosine concentrations determined twice weekly. Uncommonly, vomiting, bowel perforation, confusion, hallucinations, headache, sedation, and euphoria have been reported. Flucytosine is contraindicated in pregnancy.

IBREXAFUNGERP

Ibrexafungerp is the first of a new class of oral glucan synthase inhibitors.[11] Although the mode of action and spectrum of activity are similar to the echinocandins, its oral bioavailability sets it apart. Its first licensed indication is for vulvovaginal candidiasis (Chapter 310), but additional indications are likely.

Mechanisms of Action

Ibrexafungerp is a noncompetitive inhibitor of β-(1,3)-D-glucan with different binding sites than the echinocandins. Amino acid mutations in either of the glucan synthase copies in *Candida* spp lead to ibrexafungerp resistance.

Ibrexafungerp is about 50% bioavailable after oral administration, with some variability among patients. Peak concentrations occur after 6 to 9 hours, and the half-life is 16 to 24 hours. It is extensively distributed to most tissues in much greater concentrations than in plasma (4- to 50-fold) but not to the brain. Metabolism is via cytochrome P-450 CYP3A4, so that greater than 90% is excreted via the liver and bile and less than 2% in urine.

Indications and Dosage

For vulvovaginal candidiasis, the dose of ibrexafungerp is 300 mg orally twice a day for a single day (see Table 307-1).[A14] Ibrexafungerp also is fungicidal for most *Candida* spp, including azole-resistant strains and *C. auris*, and it is fungistatic for *Aspergillus* spp. It also has good activity against *Penicillium* spp, most dermatophytes, *Paecilomyces variotii*, *Scytalidium dimidiatum*, *Alternaria* spp, and *Cladosporium* spp, with some activity against the multiresistant *Lomentospora prolificans*. Activity against *C. lusitaniae* and *C. krusei* is lower than other *Candida* spp. Ibrexafungerp has potent activity against most, but not all, echinocandin-resistant *C. glabrata*.

Drug Interactions

Blood levels of ibrexafungerp may increase if given in combination with strong CYP3A4 inhibitors such as diltiazem. Lower concentrations of ibrexafungerp are likely if given concomitantly with rifampin, carbamazepine, phenytoin, St. John's wort, bosentan, efavirenz, or etravirine.

Adverse Effects

The most common adverse events during therapy are diarrhea, nausea, abdominal discomfort, vomiting and light-headedness. Unusual or rare side effects include dysmenorrhea, flatulence, back pain, elevated transaminases, vaginal bleeding, or skin rash. Ibrexafungerp is teratogenic in some experimental animals and is contraindicated in pregnancy.

OTHER AGENTS

Combinations of antifungal agents with different mechanisms of action are increasingly used to cover possible resistant pathogens, overcome the relatively high frequency of low serum concentrations of voriconazole in certain clinical situations (e.g., intensive care), and improve the very poor response rates in some diseases. Although synergy in vitro may be relatively easy to demonstrate, there are few examples of synergy in animal model studies and even fewer in patients. The clinical advantages of the amphotericin-flucytosine combination in cryptococcosis have yet to be documented definitively in other situations.

Immunomodulators, particularly cytokines, hold promise, but insufficient clinical data exist to determine where and how these drugs might be used. Granulocyte-macrophage colony-stimulating factor can improve outcomes when given prophylactically to high-risk leukemia patients during induction therapy.[A15] Gamma interferon can help preserve graft function in renal transplant patients with invasive aspergillosis and reduce hospitalization in patients who have chronic pulmonary aspergillosis and are low producers of gamma interferon.[12]

Therapy for the various forms of tinea and of onychomycosis with systemic agents is discussed in Chapter 405. Terbinafine, which is useful in these settings, is rarely effective in other mycoses unless the mycosis involves only the skin. Although *Pneumocystis jirovecii* is now classified among the fungi, the drugs used to treat it are not used to treat other mycoses (Chapter 313).

308 ENDEMIC MYCOSES

GEORGE R. THOMPSON, III, AND MARISA H. MICELI

BLASTOMYCOSIS

DEFINITION

Blastomycosis (North American blastomycosis) is an endemic mycosis that primarily causes infection of the lungs and skin and, less commonly, infection of the osteoarticular and genitourinary systems[1] (Table 308-1).

The Pathogen

Blastomyces spp. are thermally dimorphic fungi, and numerous new species have been recently identified.[2] In the mold phase in the environment, the organism produces conidia, which when aerosolized and inhaled cause infection. At 37° C on culture media and in tissues, the organism is a distinctive appearing yeast that is 5 to 20 μm in diameter with a thick refractile cell wall, and single broad-based buds (Fig. 308-1).

EPIDEMIOLOGY

Blastomyces spp. exist in diverse geographic areas worldwide, but most cases of blastomycosis are reported from the south central and north central regions of the United States[3] and the Canadian provinces surrounding the Great Lakes. Blastomycosis also occurs in Africa and the Middle East.[4] The natural niche of *B. dermatitidis* is thought to be soil and decaying vegetation, especially in areas associated with rivers and lakes. Although most cases occur sporadically, several well-described outbreaks have occurred, often in association with activities along waterways. The typical patient with blastomycosis is a middle-aged man who has an outdoor occupation or hobby. Blastomycosis develops in both hunters and their dogs in endemic areas.

PATHOBIOLOGY

After the inhalation of conidia, *B. dermatitidis* transforms into the yeast phase and causes pulmonary infection. Although most patients manifest only pulmonary symptoms, others have cutaneous lesions in the absence of other organ involvement or have disseminated infection. It is likely that most patients have asymptomatic hematogenous dissemination after the initial pulmonary infection, so cutaneous lesions should be viewed as a manifestation of hematogenous spread of the organism. Except in rare instances, blastomycosis is not acquired by inoculation. Cellular immunity involving T lymphocytes and macrophages is an important component of the host response to infection with *B. dermatitidis*, but neutrophils also play a role. Most patients with blastomycosis are healthy. Patients who are immunosuppressed are more likely to have severe disease. Infection in an immunosuppressed host can occur after new exposure to *Blastomyces* spp. or less often, from reactivation of a latent focus of infection acquired years earlier.

CLINICAL MANIFESTATIONS

Pulmonary

Most patients with acute pulmonary blastomycosis are asymptomatic or are thought to have community-acquired pneumonia. Patients with acute

308 ENDEMIC MYCOSES

GEORGE R. THOMPSON, III, AND MARISA H. MICELI

BLASTOMYCOSIS

DEFINITION

Blastomycosis (North American blastomycosis) is an endemic mycosis that primarily causes infection of the lungs and skin and, less commonly, infection of the osteoarticular and genitourinary systems[1] (Table 308-1).

The Pathogen

Blastomyces spp. are thermally dimorphic fungi, and numerous new species have been recently identified.[2] In the mold phase in the environment, the organism produces conidia, which when aerosolized and inhaled cause infection. At 37° C on culture media and in tissues, the organism is a distinctive appearing yeast that is 5 to 20 μm in diameter with a thick refractile cell wall, and single broad-based buds (Fig. 308-1).

EPIDEMIOLOGY

Blastomyces spp. exist in diverse geographic areas worldwide, but most cases of blastomycosis are reported from the south central and north central regions of the United States[3] and the Canadian provinces surrounding the Great Lakes. Blastomycosis also occurs in Africa and the Middle East.[4] The natural niche of *B. dermatitidis* is thought to be soil and decaying vegetation, especially in areas associated with rivers and lakes. Although most cases occur sporadically, several well-described outbreaks have occurred, often in association with activities along waterways. The typical patient with blastomycosis is a middle-aged man who has an outdoor occupation or hobby. Blastomycosis develops in both hunters and their dogs in endemic areas.

PATHOBIOLOGY

After the inhalation of conidia, *B. dermatitidis* transforms into the yeast phase and causes pulmonary infection. Although most patients manifest only pulmonary symptoms, others have cutaneous lesions in the absence of other organ involvement or have disseminated infection. It is likely that most patients have asymptomatic hematogenous dissemination after the initial pulmonary infection, so cutaneous lesions should be viewed as a manifestation of hematogenous spread of the organism. Except in rare instances, blastomycosis is not acquired by inoculation. Cellular immunity involving T lymphocytes and macrophages is an important component of the host response to infection with *B. dermatitidis*, but neutrophils also play a role. Most patients with blastomycosis are healthy. Patients who are immunosuppressed are more likely to have severe disease. Infection in an immunosuppressed host can occur after new exposure to *Blastomyces* spp. or less often, from reactivation of a latent focus of infection acquired years earlier.

CLINICAL MANIFESTATIONS

Pulmonary

Most patients with acute pulmonary blastomycosis are asymptomatic or are thought to have community-acquired pneumonia. Patients with acute

ABSTRACT

The endemic mycoses are caused by dimorphic fungi that exist as molds in the environment and convert to a yeast form or, in the case of *Coccidioides* species, a spherule, in the body and at 37° C. Endemic mycoses are geographically restricted, and infection is acquired from the environment and not transmitted person-to-person. The prominent diseases in North America are coccidioidomycosis, histoplasmosis, and blastomycosis. *Coccidioides* species are found in the desert southwest, and *Histoplasma* spp. and *Blastomyces* spp. are most often, but not exclusively, found in the Midwest. Initial infection is often asymptomatic but can progress to cause a spectrum of pulmonary findings, including respiratory distress. All these organisms can cause disseminated disease involving many organs, especially in immunocompromised patients. *Paracoccidioides* spp. are found in the soil in South America; most commonly, symptomatic disease develops in farm laborers years after the initial exposure. Sporotrichosis has a worldwide distribution; it differs from the other endemic mycoses in that it almost always follows direct inoculation of the organism through the skin, where it causes localized subcutaneous infection. Standardized diagnostic criteria can distinguish proven and probable disease from colonization. Treatment depends on the organism and the severity of the illness. The duration of treatment, except for sporotrichosis, is generally 3 to 6 months.

KEYWORDS

blastomycosis
histoplasmosis
coccidioidomycosis
sporotrichosis
paracoccidioidomycosis
environmental exposure
endemic mycosis

pneumonia have fever, malaise, a nonproductive cough, and a pulmonary infiltrate that shows lobar or multilobar patchy or nodular infiltrates on chest radiographs. Development of classic, verrucous draining skin lesions is a strong clue for blastomycosis.

Chronic pulmonary blastomycosis must be differentiated from tuberculosis (Chapter 299), other fungal infections, and lung cancer (Chapter 177). Fever, night sweats, weight loss, fatigue, cough, sputum production, hemoptysis, and dyspnea are commonly noted. On chest radiograph, the lesions are cavitary, nodular, fibrotic, or masslike in appearance. Hilar and mediastinal lymphadenopathy and pleural effusions are not commonly observed. Overwhelming pulmonary disease with acute respiratory distress syndrome (ARDS) occurs infrequently.[5]

Disseminated Infection

Cutaneous lesions are the most common manifestation of disseminated blastomycosis. The lesions, which can be single or multiple, are usually well circumscribed and painless (Fig. 308-2). Papules, nodules, plaques, and ulcers can occur; often they are verrucous and develop multiple punctate draining areas in the center. The lesions clinically mimic those associated with nontuberculous mycobacteria, other fungal infections, or pyoderma gangrenosum (Table 408-5). An uncommon manifestation, seen in immunocompromised patients, is the appearance of pustular lesions that readily reveal the organism when aspirated.

Another manifestation of disseminated blastomycosis is osteoarticular involvement. Osteomyelitis can be associated with contiguous skin lesions or can appear at sites distant from cutaneous lesions. Genitourinary involvement may be asymptomatic or be associated with signs of prostatism and the presence of a nodule on digital examination. Infrequent findings include laryngeal and oropharyngeal nodules; ocular lesions; central nervous system (CNS) involvement with either meningitis or intracerebral mass lesions; and dissemination to the liver, spleen, and lymph nodes.

DIAGNOSIS

The definitive diagnostic test for blastomycosis is growth of the organism from an aspirate, tissue biopsy specimen, sputum, or body fluid.[6] The mold phase takes several weeks to grow at room temperature. Once growth has occurred, the organism can be rapidly identified as *Blastomyces* spp. with a highly specific and sensitive DNA probe.

In this setting, the distinctive large, thick-walled yeast with a single broad-based bud (see Fig. 308-1) may be identified by: histopathologic examination of cutaneous or pulmonary lesions; cytologic examination of sputum, bronchoalveolar lavage fluid, or other tissue fluids; or calcofluor fluorescent staining of sputum or purulent material from pustular lesions. Identification of characteristic organisms on histopathology allows a tentative diagnosis of blastomycosis and initiation of antifungal therapy before culture results are known.

An enzyme immunoassay for *B. dermatitidis* cell wall antigens is available for use on serum, urine, or bronchial alveolar lavage fluid. The sensitivity of this assay varies with different reports. Because *B. dermatitidis* and *H. capsulatum* share many cell wall antigens, this assay is often positive in patients with histoplasmosis, as well as in those with blastomycosis.

It is helpful to obtain a bone scan in all patients with disseminated blastomycosis because of its propensity to infect bone.

FIGURE 308-2. Skin lesion—blastomycosis. A well-circumscribed painless ulcer in a patient with disseminated blastomycosis.

TREATMENT

With the exception of patients who have acute pulmonary blastomycosis that has totally resolved before the diagnosis is established, all patients with blastomycosis should be treated with an antifungal agent.[7] Patients who have mild-to-moderate pulmonary or disseminated blastomycosis should be treated with itraconazole (oral solution or capsules 200 mg three times a day for 3 days then once or twice daily for 6 to 12 months) to achieve mycologic cure and prevent relapse. If itraconazole is not tolerated, voriconazole or posaconazole can be used under expert guidance. The echinocandins are not active against *B. dermatitidis* and should not be used.

Patients who have severe pulmonary or disseminated blastomycosis, all patients with CNS infection, and most immunosuppressed patients should be treated initially with a lipid formulation of amphotericin B. The dosage is 3 to 5 mg/kg IV daily, except for CNS infection, for which 5 mg/kg IV daily should be used. After clinical improvement has occurred, usually within 1-2 weeks, therapy can be changed to itraconazole (oral solution or capsules, 200 mg three times a day for 3 days then twice daily) for a total of at least 12 months of therapy. For all patients who are treated with itraconazole, serum itraconazole levels should be determined when steady state has been reached after 2 weeks of therapy to ensure adequate absorption. Serum concentrations should be greater than 1 μg/mL.[8]

Corticosteroids have been helpful as adjunctive therapy for patients with blastomycosis-associated acute respiratory distress syndrome (ARDS) (Chapter 90), but this practice remains controversial. In patients who remain seriously hypoxic despite mechanical ventilation, extracorporeal membrane oxygenation may be lifesaving.

PROGNOSIS

The prognosis for patients with pulmonary or disseminated blastomycosis is excellent; more than 90% are cured. Most reported deaths occur in patients with overwhelming pneumonia and ARDS. In patients who require mechanical ventilation, the mortality rate is about 40%.[9]

HISTOPLASMOSIS

DEFINITION

Histoplasmosis is the most common endemic mycosis in the United States. Most infections are self-limited, but the organism has the ability to cause acute and chronic pulmonary infections as well as disseminated infection (Table 308-2).

TABLE 308-2 HISTOPLASMOSIS: CLINICAL CHARACTERISTICS AND TREATMENT

CHARACTERISTIC	DESCRIPTION
Causative fungi	*Histoplasma capsulatum* var *capsulatum* and other *Histoplasma* spp.
Primary geographic distribution	North and Central America. Endemic in the Mississippi and Ohio River Valleys, with extension into the St. Lawrence Basin
Primary route of acquisition	Respiratory (inhalation of microconidia)
Principal site of disease	Lungs and mediastinal lymph nodes most common; spread to skin, bone marrow, meninges, and other viscera uncommon but serious
Opportunistic infection in compromised hosts	Diffuse pneumonia and widespread infections common in patients with T-cell defects or during high-dose corticosteroid therapy or TNF-α inhibitors
Drug of choice for most patients	No antifungal is required for uncomplicated pneumonia; itraconazole for mild to moderate pulmonary histoplasmosis. Lipid formulation amphotericin B for moderate to severe/disseminated disease
Alternative therapy	Fluconazole, posaconazole

The Pathogen

Histoplasma capsulatum var *capsulatum* is a thermally dimorphic fungus. In the environment and at temperatures lower than 35° C, it exists as a mold that produces conidia. It produces both tuberculate macroconidia, which are helpful for identification purposes in the laboratory, and microconidia, which are the infectious form. In tissues and at 35 to 37° C, *H. capsulatum* converts into 2- to 4-μm oval yeasts that reproduce by budding and parasitize macrophages. African histoplasmosis is caused by a different subspecies, *H. capsulatum* var *duboisii*, and has different disease manifestations, particularly involvement of skin, subcutaneous tissues, lymph nodes, and bone but only rarely the lungs or other internal organs.

EPIDEMIOLOGY

Histoplasmosis, though found worldwide, is primarily a disease of North and Central America. *H. capsulatum* is endemic in the Mississippi and Ohio River Valleys, with extension into the St. Lawrence Basin; microfoci exist in discrete isolated areas in several eastern states and may represent novel species. Soil, caves, and abandoned buildings that contain high concentrations of bird or bat guano support growth of the organism. Every year, thousands of individuals who live in areas endemic for *H. capsulatum* are infected. Most cases are sporadic, and the exact source of exposure is unknown. Point source outbreaks occur in association with disruption of soil; cleaning attics, bridges, or barns; renovating or tearing down old structures laden with guano; and spelunking.

PATHOBIOLOGY

After inhalation of microconidia into the alveoli, a localized pulmonary infection ensues. Neutrophils and macrophages phagocytize the organism, which is now in the yeast phase. The organism is able to survive and travels within macrophages to the hilar and mediastinal lymph nodes and throughout the reticuloendothelial system by hematogenous dissemination. Such dissemination, which probably occurs in most persons who are infected, is typically asymptomatic in normal hosts. After several weeks, T-cells specifically sensitized by *Histoplasma* antigens activate macrophages, which are then able to kill the intracellular fungi.

The extent of disease is determined by both the number of conidia inhaled and the immune response of the host. A small inoculum can cause severe infection in immunosuppressed patients. Persons at greatest risk include patients who have acquired immunodeficiency syndrome (AIDS), lymphoma, or are organ transplant recipients, as well as patients who are taking corticosteroids or tumor necrosis factor inhibitors.[10] Reactivation of latent infection occurs in patients who have deficient cell-mediated immunity, as evidenced by the occurrence of histoplasmosis in immunosuppressed persons who grew up in the endemic area but have not returned to that area for years.

CLINICAL MANIFESTATIONS

Acute Pulmonary Histoplasmosis

Most individuals infected with *H. capsulatum* are asymptomatic. Patients who develop symptomatic pulmonary infection usually have a self-limited illness that begins several weeks after exposure and is characterized by fever, chills, fatigue, nonproductive cough, anterior chest discomfort, and myalgias. The chest radiograph typically shows a patchy lobar or multilobar reticulonodular infiltrate.[11]

Acute pulmonary histoplasmosis can be life-threatening. In patients who have experienced heavy exposure to *Histoplasma* spp., as might occur during the demolition of old buildings or while spelunking in a heavily infested cave, and in those who are immunosuppressed, high spiking fevers, chills, prostration, dyspnea, and cough are prominent, and ARDS can occur.

Chronic Pulmonary Histoplasmosis

Chronic cavitary pulmonary histoplasmosis is a progressive, often fatal form of histoplasmosis that develops almost exclusively in older patients who have chronic obstructive pulmonary disease (Chapter 76). Symptoms include fever, fatigue, anorexia, weight loss, cough productive of purulent sputum, and hemoptysis. On chest radiography the usual findings are unilateral or bilateral upper lobe infiltrates with multiple cavities and extensive fibrosis in the lower lobes.

Complications of Pulmonary Histoplasmosis

The mediastinal and hilar lymph nodes frequently calcify as the infection resolves; years later they can erode into bronchi and cause hemoptysis and expectoration of broncholiths. Granulomatous mediastinitis is an uncommon syndrome characterized by continuing inflammation and necrosis in the mediastinal lymph nodes. The enlarged nodes are readily apparent on chest radiographs, and computed tomography (CT) shows central necrosis and, in some cases, impingement on adjacent structures, including the esophagus, airways, and blood vessels. Although the symptoms usually resolve without treatment, obstructive syndromes can be severe, and the nodes can persist for years.

Fibrosing mediastinitis is a rare complication of histoplasmosis in which the host responds to the infection with an inappropriate excessive fibrotic response. Obstruction of the airways, superior vena cava, or pulmonary arteries and veins can occur with resultant progressive right heart failure and respiratory insufficiency. Bilateral obstruction of the pulmonary vasculature is less common than unilateral involvement and carries a worse prognosis. Mediastinal widening is seen on chest radiographs, and CT and angiography define the extent of invasion and obstruction of mediastinal structures. Pericarditis (Chapter 62) is a manifestation of a local inflammatory reaction to adjacent histoplasmosis.

Disseminated Histoplasmosis

Symptomatic acute disseminated histoplasmosis occurs mostly in immunosuppressed patients, especially patients who have AIDS with CD4+ counts lower than 150/μL as well as patients who have a hematologic malignancy, have received an organ transplant, or are taking corticosteroids or tumor necrosis factor inhibitors. Symptoms and signs include chills, fever, anorexia, weight loss, hypotension, dyspnea, hepatosplenomegaly, and skin and mucous membrane lesions. Pancytopenia, diffuse pulmonary infiltrates on chest radiography and CT, findings of disseminated intravascular coagulation (Chapter 161), and acute respiratory failure can be seen.

Chronic progressive disseminated histoplasmosis is an uncommon, fatal form of histoplasmosis that occurs mostly in middle-aged to elderly persons who have no known immunosuppressive illness. The illness is characterized by fever, night sweats, weight loss, anorexia, and fatigue. Patients appear chronically ill, hepatosplenomegaly and mucocutaneous ulcerations are common, and adrenal insufficiency (Chapter 208) can develop. An increased erythrocyte sedimentation rate, elevated alkaline phosphatase level, pancytopenia, and diffuse reticulonodular infiltrates on chest radiography and CT are typical. Patients with this form of histoplasmosis often have fever of unknown origin (Chapter 259). Miliary tuberculosis (Chapter 299), lymphoma (Chapters 171 and 172), and sarcoidosis (Chapter 83) must be excluded.

Involvement of almost every organ system has been reported with disseminated infection. Adrenal insufficiency (Chapter 208) must be excluded in any patient who has unexplained hypotension, hyponatremia, and hyperkalemia. Abdominal CT shows markedly enlarged adrenal glands. Central nervous system involvement manifests as either meningitis or focal lesions seen on magnetic resonance imaging and is more common in patients with AIDS. Skin lesions, which are also more common in patients with AIDS, can be papular, pustular, or ulcerated. *Histoplasma* endocarditis is a rare form of disseminated infection.

DIAGNOSIS

Identifying the Organism

Because the clinical manifestations of histoplasmosis are nonspecific,[12] diagnosis depends upon identifying the organism.[13] The definitive diagnostic test for histoplasmosis is growth of the organism in culture. Unfortunately, *Histoplasma* spp. may require as long as 6 weeks to grow in vitro. Tissue samples, bronchoalveolar lavage fluid, sputum, and blood are appropriate for culture. For patients who have evidence of dissemination, blood cultures are best performed with the lysis-centrifugation (Isolator tube) system; bone marrow and liver biopsy material often yield *Histoplasma* in disseminated disease. If pulmonary histoplasmosis is a diagnostic consideration, the laboratory should be informed so that a special medium that decreases the growth of commensal fungi can be used for the culture of pulmonary samples. As soon as growth of a mold has been detected, highly specific DNA probes for *Histoplasma* spp. allow rapid identification of the organism.

If the patient is acutely ill, tissue biopsy should be performed to search for the distinctive 2- to 4-μm oval yeasts with single buds (Fig. 308-3), which allows a tentative diagnosis to be made as quickly as possible. Routine tissue stains do not show yeasts; biopsy material must be stained with methenamine silver or periodic acid–Schiff stains. In patients with disseminated disease, bone marrow, liver, skin, and mucocutaneous lesions usually reveal many

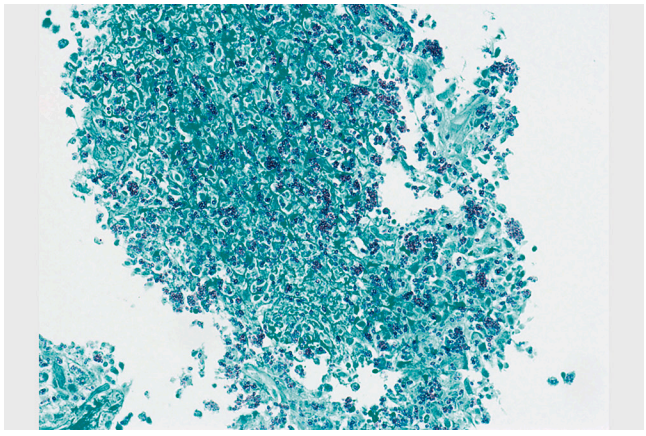

FIGURE 308-3. Tissue biopsy in a patient with histoplasmosis. Distinctive 2-4 µm oval yeast, each with a single bud.

organisms. The organisms also can be seen within neutrophils in peripheral blood smears from patients with acute disseminated infection. In patients with chronic pulmonary histoplasmosis or granulomatous mediastinitis, biopsy of the lung or lymph nodes may reveal the organism.

Serology plays an important role in the diagnosis of both acute and chronic forms of histoplasmosis.[14] A four-fold rise in complement fixation titer or the appearance of an M band by immunodiffusion assay is very suggestive of histoplasmosis. Serology is rarely helpful in immunosuppressed patients, who often cannot mount an antibody response. Because serologic tests are not definitive in patients with mediastinal lymphadenopathy, the results always should be confirmed by tissue biopsy.

An *H. capsulatum* enzyme immunoassay, which can detect polysaccharide antigen and detect the antigen in urine and serum, is extremely helpful in patients with disseminated infection and/or acute pulmonary infection. A serum immunoassay is positive in as many as 90% of patients with acute pulmonary histoplasmosis. Almost 75% of patients who have experienced heavy exposure and demonstrate diffuse pulmonary infiltrates and more than 90% of patients who have disseminated histoplasmosis have a positive urinary antigen test. The assay is less useful for patients who have chronic cavitary histoplasmosis and not useful for granulomatous or fibrosing mediastinitis. PCR testing can be helpful if culture and serology are negative.

The differential diagnosis of acute pulmonary histoplasmosis includes pneumonia from *Blastomyces* spp., *Mycoplasma pneumoniae* (Chapter 293), *Legionella* spp. (Chapter 290), and *Chlamydia pneumoniae* (Chapter 294). When enlarged hilar or mediastinal lymph nodes are present, histoplasmosis should be strongly considered. The most difficult diagnosis to differentiate is for acute pulmonary blastomycosis because the endemic areas overlap, a comparable history of outdoor activities is often obtained, and radiographs show similar findings. The clinical presentation and radiological findings of chronic pulmonary histoplasmosis may mimic tuberculosis (Chapter 299), other fungal pneumonias (especially blastomycosis), and nontuberculous mycobacterial infections (Chapter 300).

Disseminated histoplasmosis is clinically indistinguishable from sepsis of any bacterial or viral cause. In patients with AIDS, the differential diagnosis includes cytomegalovirus (Chapter 347), disseminated *Mycobacterium avium* complex infection (Chapter 300), and tuberculosis (Chapter 299).

TREATMENT

Itraconazole is the drug of choice for mild-to-moderate histoplasmosis. Lipid formulations of amphotericin B should be used as initial therapy for severe, life-threatening infections. Posaconazole has been used in fewer patients but appears to be effective. Fluconazole is less active and should be considered a second-line agent. The echinocandins are not effective for histoplasmosis.

Pulmonary Histoplasmosis

For acute pulmonary histoplasmosis, treatment is not usually given because the diagnosis often is not made until after the symptoms have resolved. However, if the patient remains symptomatic for at least 4 weeks, therapy with itraconazole (oral solution or capsules, 200 mg three times a day for 3 days and then once or twice daily) for 6 to 12 weeks should be given.

All patients who have severe pulmonary histoplasmosis and all immunosuppressed patients should be treated with an antifungal agent.[15] Lipid formulations of amphotericin B (3 to 5 mg/kg/day) are recommended for several weeks until a response is noted, at which time therapy can be changed to oral itraconazole (200 mg three times daily for 3 days and then 200 mg twice daily). A short course of methylprednisolone is recommended under expert guidance for patients in whom respiratory distress develops in association with acute pulmonary histoplasmosis.

For chronic pulmonary histoplasmosis antifungal therapy should be given to all patients. Itraconazole (200 mg three times a day for three days and then twice daily for 12 to 24 months), is recommended. Itraconazole levels should be monitored in all patients to ensure adequate absorption and therapeutic levels are achieved.

A trial of itraconazole for 6 to 12 weeks is often given to patients who have symptomatic granulomatous mediastinitis, although no data prove such therapy to be effective. Surgical resection of lymph nodes that cause obstructive symptoms may be beneficial. Antifungal therapy offers no benefit for patients who have fibrosing mediastinitis. Surgery is not indicated and carries a high operative mortality rate. Intravascular stents have been used successfully in patients who have vascular obstruction.

Disseminated Histoplasmosis

All patients with symptomatic disseminated histoplasmosis should receive antifungal therapy. Patients who have only mild-to-moderate symptoms with acute disseminated disease and many patients with chronic progressive disseminated histoplasmosis can be treated with itraconazole (200 mg twice daily after a loading dose of 200 mg three times daily for 3 days). A total of 12 months of therapy is generally adequate, but patients with chronic progressive disease may need longer treatment.

Patients who have moderately severe to severe disseminated histoplasmosis should be treated with liposomal amphotericin B (3 mg/kg/day). Therapy can be changed to itraconazole (see earlier) after the patient has responded to amphotericin to complete a total of 12 months of therapy. For patients who are immunosuppressed, therapy with itraconazole (200 mg/day) should continue until the immunosuppression resolves. For patients with AIDS (Chapter 358), suppressive therapy can be safely stopped in patients who have had a year of therapy, are receiving antiretroviral therapy, have CD4+ counts greater than 150 cells/µL, and have an undetectable HIV blood viral load for at least 6 months.[16]

Patients with pericarditis (Chapter 62) respond promptly to anti-inflammatory medications without antifungal therapy. Hemodynamic compromise, though unusual, requires drainage of pericardial fluid; only rarely has progression to constrictive pericarditis been documented.

PREVENTION

Prevention of histoplasmosis is difficult because exposure can occur without the person's knowledge in highly endemic areas. Persons who are immunosuppressed should be advised to avoid demolition areas, spelunking, and cleaning of farm buildings or attics. In patients with AIDS, itraconazole (200 mg/day) is effective for preventing infection and is indicated for patients whose CD4+ counts are lower than 150/µL and who live in a highly endemic area with a rate of histoplasmosis that is greater than 10 cases per 100 patient years. Neither primary or secondary prophylaxis is currently recommended for other immunosuppressed patients (e.g., solid organ transplant recipients).

PROGNOSIS

Acute pulmonary histoplasmosis is usually a self-limited disease. Patients who require treatment generally respond promptly to antifungal agents. However, the response of patients with chronic cavitary pulmonary histoplasmosis is often poor, primarily because of their severe underlying pulmonary disease. Mediastinal fibrosis has a poor prognosis, but intravascular stenting has led to improvement in many patients.

Patients with disseminated histoplasmosis, even those with advanced AIDS, usually respond promptly to antifungal therapy; most deaths in immunosuppressed patients occur when the diagnosis is delayed. Older patients with chronic progressive disseminated histoplasmosis have a slower but usually complete response to therapy.

COCCIDIOIDOMYCOSIS

DEFINITION

Coccidioidomycosis is a systemic fungal infection caused by *Coccidioides* spp. endemic to some arid regions of the western hemisphere (Table 308-3).

The Pathogen

Coccidioides immitis and *C. posadasii* are dimorphic fungi classified as Ascomycetes by ribosomal gene homology. In their vegetative state, mycelia

TABLE 308-3 COCCIDIOIDOMYCOSIS: CLINICAL CHARACTERISTICS AND TREATMENT

CHARACTERISTIC	DESCRIPTION
Causative fungi	*Coccidioides immitis* and *Coccidioides posadasii*
Primary geographic distribution	Arid regions of the western hemisphere, including parts of Arizona, California, New Mexico, and Washington; western Texas; parts of Central and South America
Primary route of acquisition	Respiratory (inhalation of arthroconidia)
Principal site of disease	Lungs most common; spread to skin, bones, meninges, and other viscera uncommon but serious
Opportunistic infection in compromised hosts	Diffuse pneumonia and widespread infections common in patients with T-cell defects or during high-dose corticosteroid therapy or TNF-α inhibitors
Drug of choice for most patients	No antifungal is required for uncomplicated pneumonia; fluconazole or itraconazole for progressive forms of infection
Alternative therapy	Amphotericin B (especially with diffuse pneumonia or rapidly progressive infections), voriconazole, posaconazole, isavuconazole

TNF = tumor necrosis factor.

with true septations mature to produce arthroconidia (spores), which are single cells approximately 2 to 5 μm in diameter. After infection, an arthroconidium enlarges to a spherule up to 75 μm in diameter and undergoes internal septation to produce scores of endospores. When the spherules rupture, endospores are released and produce more spherules in infected tissue or revert to mycelia if removed from the body.

EPIDEMIOLOGY

Coccidioides organisms can be recovered from the soil of the low deserts of Arizona; Los Angeles County and the Central Valley of California; parts of other states, including New Mexico, Nevada, and Texas[17,18]; and parts of Central and South America. Isolated pockets of endemicity also have been found unexpectedly elsewhere, such as in Washington State. Coccidioidomycosis is endemic in arid regions, which are characterized by modest rainfall, mild winters, and low humidity. However, even in the most highly endemic areas, fungal colonies are sparse and occupy only a tiny fraction of the total acreage. Mycelia multiply during periods of rain, and arthroconidia develop as the soil dries. Rates of infection are highest during dry months, occasionally accentuated when soil is disturbed by windstorms or construction equipment. Exposure to contaminated bales of cotton or other fomites can rarely result in infection beyond the endemic regions.

In general, the annual risk for infection within the most strongly endemic areas is 3%, thereby resulting in approximately 150,000 new infections per year. Reported clinical illness following infection is increasing. For example, from 1998 to 2016, reported infections increased more than 10-fold in California. With unusually intense exposure, such as archaeology sites or during military maneuvers within endemic regions, infections can develop in most individuals who are exposed for as little as a few days.

PATHOBIOLOGY

Inhaling even a single arthroconidium to the level of the terminal bronchiole may cause infection. Fungal proliferation engenders granulomatous inflammation, which is associated with intact spherules, and acute inflammation, which includes eosinophils and is associated with spherule rupture and proliferation. Focal pneumonia is often associated with ipsilateral hilar adenopathy; less frequently, infection enlarges the paratracheal, supraclavicular, and cervical nodes. Lesions occurring elsewhere are the result of hematogenous dissemination, and most become apparent within 2 years of the initial infection.[19] Although progressive dissemination occurs in less than 1% of infections, as many as 8% of persons with self-limited infection manifest asymptomatic chorioretinal scars, thereby suggesting that subclinical hematogenous spread may be frequent. Within weeks after infection, durable T-cell immunity normally arrests fungal proliferation, allows the inflammation to resolve, and prevents reinfection in the future. However, control of the infection occurs without sterilizing existing lesions, so reactivation of the dormant infection is possible even many years later in patients whose cell-mediated immunity becomes deficient. Arthritic and dermatologic manifestations or primary infection are mediated by circulating immune complexes or other immunologic phenomena rather than by fungal dissemination.

CLINICAL MANIFESTATIONS

About two thirds of infections are asymptomatic[20] and are detected only by finding dermal hypersensitivity to coccidioidal antigens. Patients who become ill usually experience pulmonary syndromes that eventually are self-limited. However, some patients develop complications or progressive forms of infection that display a broad variety of manifestations and pose difficult management problems.

Primary Pulmonary Infections

Symptoms develop within 5 to 21 days after exposure. For residents of, or recent visitors to, southern Arizona or the Central Valley of California, coccidioidomycosis accounts for approximately 25% of cases of community-acquired pneumonia. Fever, weight loss, fatigue, dry cough, and pleuritic chest pain are common but nonspecific complaints.[21] Arthralgia of multiple joints without significant effusion is also frequent and is referred to as "desert rheumatism." Occasional skin manifestations include a short-lived nonpruritic maculopapular rash, erythema multiforme, or erythema nodosum. Both joint and skin lesions resolve without tissue destruction.

Radiographs of the chest may not detect any abnormalities or may demonstrate pulmonary infiltrates that are either segmental or lobar. Hilar adenopathy is often a distinctive finding. Parapneumonic pleural effusions may occur and generally resolve without intervention. Eosinophilia may be a prominent finding in differential leukocyte counts of peripheral blood, and the erythrocyte sedimentation rate is generally elevated. Symptoms frequently persist for many weeks before improvement is clearly underway, and the illness, especially lassitude, may persist for months.

Extrapulmonary Dissemination

Coccidioidomycosis in patients with deficiencies in cellular immunity, such as solid organ recipients, patients receiving other immunosuppressive therapy, those with AIDS or lymphoma, and women during their third trimester of pregnancy, usually results in dissemination beyond the lungs.[22] Mutations of interferon-γ or the interleukin-12 receptor genes also predispose to dissemination. However, disseminated infection occurs in some patients who have no obvious underlying disease and do not manifest heightened susceptibility to other infections. Disseminated infection is more likely to occur in men than in women and in persons of certain ancestry such as Africans, Filipinos, or Native Americans compared to Caucasians. The most common locations for disseminated lesions are the skin (cutaneous papules or subcutaneous abscesses); joints (especially the knee); bones, including the vertebrae; and basilar meninges. Such infections may produce one or many lesions and are frequently subacute or chronic in their manifestation. In broadly immunosuppressed patients, coccidioidal infections may be more fulminant, with fungemia detectable in blood cultures and the development of diffuse reticulonodular pulmonary infiltrates. Although the kidneys and the urinary bladder are rarely involved, *Coccidioides* may be recovered from concentrated specimens of urine, usually because of focal dissemination to the prostate. In contrast to histoplasmosis, the gastrointestinal tract is rarely involved in coccidioidomycosis.

DIAGNOSIS

Since clinical manifestations are nonspecific, diagnosis depends on methods that identify the organism. Delayed-type hypersensitivity skin testing can identify past infection with *Coccidioides* species but cannot be relied upon to diagnose ongoing active infection.

The diagnosis is definitively established by recovering *Coccidioides* spp. from clinical specimens. On direct examination of respiratory specimens or tissue, spherules appear as large structures with refractile walls and internal organization; they are also seen on hematoxylin-eosin, silver, or periodic acid–Schiff stains of histologic preparations. Gram stain does not detect spherules. In culture, mycelial growth is often evident within the first week of incubation, and PCR allows rapid genus identification. Recovery of *Coccidioides* spp. from scant respiratory secretions or from the cerebrospinal fluid of patients with meningitis may be difficult. In patients who have pleural effusion, cultures of pleural biopsies usually yield *Coccidioides* spp.

A presumptive diagnosis of coccidioidal infection is often based on the detection of specific antibodies in serum, which are about 84% sensitive and about 96% specific. Within the first weeks of the initial infection, a precipitin-type antibody is detected (IgM), usually by immunodiffusion techniques. Later,

complement fixation–type antibodies (IgG) generally appear. However, these tests may be falsely negative as often as half the time during the first weeks of illness. When reported quantitatively, concentrations of complement fixation antibodies are usually highest in the most extensive infections and decrease in patients whose infections are controlled.[23] PCR testing can be highly sensitive and specific when available.[24,25]

An important means of diagnosing coccidioidal meningitis is the detection of *Coccidioides* antigen or complement fixation antibodies in cerebrospinal fluid, along with other abnormalities such as leukocytosis, an elevated protein concentration, and a low glucose concentration. Eosinophilia of the CSF can suggest coccidioidomycosis but is not always present.

TREATMENT

The role of antifungal therapy for primary uncomplicated infections is unsettled because it is not known whether treatment either shortens the course of symptoms or diminishes the rate of complications.[26] However, the value of treatment is clear for patients with progressive or disseminated infection.

Because many coccidioidal infections are chronic, initial treatment often consists of oral azole antifungal agents, such as fluconazole and itraconazole.[27] Responses to these two medications are similar, but itraconazole is preferred in patients with skeletal infections. Doses of these azoles are 400 mg/day or higher, and treatment is usually continued for a year or more. Satisfactory responses are obtained in approximately two-thirds of patients. Fluconazole is effective therapy for coccidioidal meningitis and has greatly reduced the number of patients treated with intrathecal amphotericin B. Unfortunately, cessation of azole therapy is often followed by a recurrence of symptoms, especially in patients who have coccidioidal meningitis. Therefore, many patients need protracted or even lifelong therapy to control disease activity. The limited evidence available for the newer azole antifungals (voriconazole, posaconazole, isavuconazole) indicates that they are also effective in some patients and are sometimes useful for refractory infections. Amphotericin B is generally preferred for patients with rapidly progressive disease or when treatment with azole antifungals has failed. Daily doses range from 0.4 to 1 mg/kg for the original deoxycholate formulation and up to 5 mg/kg per day for newer lipid formulations. In addition to antifungal medications, necrotic tissue may need to be removed surgically.

Diagnosis and Treatment of Complications of Primary Pulmonary Infection

The primary pulmonary process can produce a variety of sequelae. The most frequent is the development of a pulmonary nodule (Fig. 308-4), typically measuring 1 to 4 cm and lying within 5 cm of the hilum. Despite their benign nature, coccidioidal nodules may cause concern because of their similarity to a malignant mass (Chapters 72 and 177). Positron emission tomography scans are typically positive. Management usually requires percutaneous needle aspiration or resection.

Another consequence of pulmonary coccidioidomycosis is cavitation of the infiltrate, which occurs in approximately 5% of cases of pneumonia. Most cavities are solitary and thin walled and reside in an upper lobe, close to the pleura. Occasionally, they produce pain, hemoptysis, or adjacent infiltrates. Mycetoma or fungus ball formation with either *Coccidioides* spp. or other colonizing molds is a complication of a coccidioidal cavity. Infrequently, a cavity ruptures into the pleural cavity, thereby resulting in pneumothorax, pyopneumothorax, or bronchopleural fistula. In many cases, this rupture is the first symptom of coccidioidal infection, especially in otherwise healthy young men. An air-fluid level in the pleural space, detectable by radiography, often helps differentiate this problem from a spontaneous pneumothorax.

Prompt surgical resection of the cavity is the preferred treatment of this complication. The least common pulmonary complication is persistent fibrocavitary infection that progresses to involvement of both lungs and requires long courses of antifungal therapy.

Person-to-person transmission of pulmonary infection has not been reported. Isolation precautions are unnecessary, even in acute care areas.

PROGNOSIS

After resolution of the initial infection, most patients maintain lifelong immunity, and infections after re-exposure are rare. However, cessation of symptoms is frequently accomplished without eradicating *Coccidioides* completely, so recurrence of the original infection many years after the original episode is a well-recognized risk, especially during any intercurrent periods of profound immunosuppression. Antifungal retreatment of rheumatic patients whose coccidioidal infections reactivate during treatment with biologic response modifiers and/or disease-modifying antirheumatic drugs appears to be safe in some patients. For patients in whom the initial infection cannot be resolved, the disease typically follows a protracted course. Although infection is more often debilitating than fatal, fulminant respiratory failure can occur. If untreated, coccidioidal meningitis is nearly always fatal within 2 years. Treated meningitis has a more favorable prognosis, but complications and relapse are still common.

SPOROTRICHOSIS

DEFINITION

Sporotrichosis is a subacute or chronic infection that is usually localized to cutaneous and lymphocutaneous structures, but pulmonary, osteoarticular, and disseminated infection can occur in patients with varying states of immunodeficiency.

The Pathogen

Sporothrix spp. are thermally dimorphic fungi. In the environment at temperatures ranging from 25° to 35° C, the organism exists as a mold and produces conidia, which are the infectious form. In tissues and at 37° C, *Sporothrix* spp. transform into the yeast phase.

EPIDEMIOLOGY

Sporothrix spp. are found worldwide in climates ranging from temperate to tropical. The organism exists in a variety of environmental niches, including soil, sphagnum moss, hay, decaying wood, and other vegetation. Infection is seen almost exclusively in persons whose vocation, avocation, or living conditions brings them into contact with the organism in the environment. Most cases of sporotrichosis are sporadic, but outbreaks have been described. For example, an extensive outbreak extended over many years in Rio de Janeiro, Brazil, mostly in children and women who were exposed to infected domestic cats.[28]

PATHOBIOLOGY

Infection, which is almost always acquired by inoculation of conidia, remains localized to the immediate and contiguous cutaneous, subcutaneous, and

FIGURE 308-5. Lymphocutaneous sporotrichosis. The lesion at the inoculation site has ulcerated. (From Watanakunakorn C. Photoquiz. *Clin Infect Dis*. 1996;22:765.)

lymphatic structures. Inhalation of conidia, which occurs less commonly, can result in pulmonary and, rarely, disseminated sporotrichosis typically in immunocompromised patients. The typical host response to infection with *Sporothrix* is a mixed neutrophilic and granulomatous reaction. Cell-mediated immunity is important in containing the infection. In individuals who have underlying illnesses, including alcohol use disorder, diabetes mellitus, and chronic obstructive pulmonary disease, *Sporothrix* spp. are more likely to involve osteoarticular structures and the lungs. Widespread dissemination develops in persons with advanced AIDS but is unusual in normal hosts.

CLINICAL MANIFESTATIONS

Lymphocutaneous

Days to weeks after inoculation of *Sporothrix* spp. conidia, a papular lesion develops at the inoculation site; the lesion becomes nodular and often ulcerates (Fig. 308-5).[29] Drainage is not grossly purulent, and the lesion is not terribly painful. Similar lesions occur along the lymphatic distribution proximal to the primary lesion. Verrucous or ulcerative fixed cutaneous lesions do not exhibit lymphatic extension. The differential diagnosis of lymphocutaneous sporotrichosis includes *Nocardia* infections (Chapter 306), atypical mycobacterial infections (especially *Mycobacterium marinum*; Chapter 300), *Leishmania braziliensis* infections (Chapter 319), and tularemia (Chapter 287).

Visceral and Osteoarticular

Pulmonary sporotrichosis occurs most often in middle-aged men who have chronic pulmonary disease and alcohol use disorder. Fever, night sweats, weight loss, fatigue, dyspnea, cough, purulent sputum, and hemoptysis are common. Chest radiographs show unilateral or bilateral upper lobe cavities with variable amounts of fibrosis and nodular lesions. The disease mimics reactivation tuberculosis (Chapter 299).

Osteoarticular sporotrichosis occurs most often in middle-aged men and more frequently in patients with alcohol use disorder. The joints most commonly affected are the knee, elbow, wrist, and ankle. Isolated bursitis, tenosynovitis, and nerve entrapment syndromes have been reported. Osteoarticular infection can follow local inoculation or can be secondary to hematogenous spread.

Disseminated sporotrichosis, manifested as widespread ulcerative cutaneous lesions with or without visceral involvement, is uncommon. Most cases have been reported in patients with advanced HIV infection.

DIAGNOSIS

Growth of *Sporothrix* spp. from culture of material aspirated from a lesion, a tissue biopsy specimen, sputum, or body fluid is the most effective method of establishing the diagnosis of sporotrichosis. Growth of the mold phase of the organism is usually evident within a few days. Histopathologic examination of biopsy material shows a mixed granulomatous and pyogenic process; the organisms are often present in small numbers and are frequently not seen. PCR testing at a fungal reference laboratory can confirm the diagnosis. Serology is less useful.

TREATMENT

Because sporotrichosis is usually a localized subacute to chronic infection, oral antifungal agents are preferred. Amphotericin B is reserved for severe infections.[30] Itraconazole is the drug of choice for lymphocutaneous sporotrichosis. The usual dosage of itraconazole is 200 mg daily, and treatment should continue for several weeks after all lesions have disappeared, generally for a total of 3 to 6 months. Saturated solution of potassium iodide (SSKI) can be used to treat sporotrichosis in resource-poor settings but currently has a limited role. The initial dose is 5 to 10 drops three times daily in water or juice, with the dose increasing over a period of several weeks to a maximum of 40 to 50 drops three times daily. SSKI has many side effects, including salivary gland swelling, metallic taste, rash, and fever; the only advantage is that it is inexpensive. Fluconazole is less effective than itraconazole but for occasional patients can be used at a dosage of 400 to 800 mg daily. Posaconazole has been used successfully under expert guidance in a few patients with sporotrichosis. Isavuconazole appears to have limited activity and voriconazole is not active against *Sporothrix* spp.

Osteoarticular and pulmonary sporotrichosis are usually treated with itraconazole (200 mg twice daily for 12 months). Longer therapy may be necessary based on the extent of disease. Other azoles are less effective, and SSKI is ineffective for these manifestations.

In a seriously ill patient with pulmonary sporotrichosis, a lipid formulation of amphotericin B at a dosage of (3 to 5 mg/kg daily) should be used as initial therapy. After the patient has shown improvement, therapy can be changed to itraconazole. A lipid formulation of amphotericin B (3 to 5 mg/kg daily) is the drug of choice for disseminated sporotrichosis. Therapy can be changed to itraconazole (200 mg twice daily) once the patient has stabilized. Patients with HIV infection and disseminated sporotrichosis should remain on lifelong maintenance therapy with itraconazole (200 mg daily).

PROGNOSIS

The prognosis for patients with cutaneous and lymphocutaneous sporotrichosis is excellent. Almost all patients are cured. Extracutaneous forms of sporotrichosis do not respond well to therapy, partly because of delays in diagnosis and partly because of the underlying diseases that are frequently found in these patients. The outcome of disseminated sporotrichosis in patients with HIV infection is less favorable but has improved in recent years with effective antiretroviral therapy.

PARACOCCIDIOIDOMYCOSIS

DEFINITION

Paracoccidioidomycosis (South American blastomycosis) is a subacute to chronic mycosis that is endemic in Central and South America. The disease is characterized primarily by pulmonary, mucous membrane, and cutaneous lesions, but disseminated disease also occurs.[31]

The Pathogen

Paracoccidioides spp. are thermally dimorphic fungi. In the environment and at temperatures below 35° C, the organisms grow as a mold. In tissues and at 37° C in vitro, the organism assumes the yeast form with multiple narrow-based daughter cells attached to the mother cell.

EPIDEMIOLOGY

Paracoccidioides spp. exist only in humid areas of Central and South America. More than 80% of cases are from Brazil. The presumed ecologic niche is in soil. The disease is most prevalent in middle-aged to elderly men from rural areas. Although the disease classically develops later in life, it is likely that initial exposure occurs many years earlier. Cases seen in areas outside Central and South America have all been linked to previous residence in the endemic area.

PATHOBIOLOGY

Paracoccidioidomycosis develops after the inhalation of aerosolized conidia encountered in the environment. Once in the alveoli, the mycelial phase converts to the yeast phase. In most patients, manifestations of disease do not develop at the time of the initial infection. The host defense mechanism against *P. braziliensis* appears to be primarily cell-mediated immunity. The histopathologic picture includes both neutrophilic and granulomatous responses. Paracoccidioidomycosis in patients with advanced HIV and in other immunosuppressed patients manifests as widespread disseminated infection. Reactivation of latent infection acquired years earlier is the presumed pathogenesis of most cases of the chronic adult form of paracoccidioidomycosis and cases that appear years after the patient has left the endemic area.

CLINICAL MANIFESTATIONS

Acute-Subacute (Juvenile) Paracoccidioidomycosis

The acute-subacute form of paracoccidioidomycosis, which occurs in less than 10% of patients, is a disease of the reticuloendothelial system with widespread dissemination to the liver, spleen, lymph nodes, and bone marrow. Patients younger than age 30 years typically have this form of paracoccidioidomycosis, but older adults, especially patients who are immunosuppressed, also can manifest this type of rapidly progressive disease. In patients with advanced HIV infection, rapid progression occurs with multiple cutaneous lesions, lymphadenopathy, hepatosplenomegaly, and hypoxemic pulmonary involvement.

Chronic (Adult) Paracoccidioidomycosis

Chronic paracoccidioidomycosis, which is slowly progressive over many years, is the form seen in more than 90% of patients. Pulmonary involvement is prominent and clinically mimics tuberculosis (Chapter 299) and other chronic fungal pneumonias.[32] Radiographically, nodular, interstitial, or cavitary lesions are seen, usually in the middle and lower lung fields. Many patients also have ulcerative or nodular mucous membrane lesions, primarily in the anterior nares, the oral cavity, and the larynx; these lesions are slowly destructive and can lead to dysphonia and stenosis of the airway. Cutaneous lesions, particularly on the face, are also common and may be papular, nodular, ulcerative, or plaquelike. The mucocutaneous lesions must be differentiated from mucocutaneous leishmaniasis and squamous cell carcinoma. Adrenal involvement has been reported in more than 90% of fatal cases at autopsy, but adrenal insufficiency (Chapter 208) is clinically noted in only about half of cases.

DIAGNOSIS

The definitive diagnosis of paracoccidioidomycosis is established by growth of *Paracoccidioides* in culture. The organism may require as long as 4 weeks to grow. For seriously ill patients, direct examination of body fluids, sputum, or purulent material treated with potassium hydroxide or calcofluor fluorescent stain or histopathologic examination of tissue biopsy samples can provide a presumptive diagnosis. The characteristic appearance of *Paracoccidioides* consists of thick-walled yeast cells that have multiple small, circumferentially attached, narrow-based budding daughter yeast cells—a distinctive morphologic picture likened to a ship's steering wheel. Polymerase chain reaction testing may be useful in tissue samples.[33]

A variety of immunodiffusion assays, enzyme immunoassays, and complement fixation assays are available in endemic areas, but sensitivity and specificity vary greatly. The immunodiffusion assay appears to be most useful.

TREATMENT

The drug of choice for the treatment of paracoccidioidomycosis is itraconazole (200 mg/day for 6 to 9 months for mild disease and for 12 to 18 months for moderate disease).[34] Voriconazole is as effective as itraconazole when used under expert guidance, and a few studies report the successful use of posaconazole and isavuconazole. Fluconazole is less effective and should not be used. Sulfonamides can be used to treat paracoccidioidomycosis inexpensively, but relapse rates are higher than with the azoles. Amphotericin B is effective but rarely used, except under expert guidance in immunosuppressed patients who have life-threatening disseminated disease. Most patients with advanced HIV have been treated with amphotericin B as initial therapy, followed by lifelong suppressive therapy with either itraconazole or trimethoprim-sulfamethoxazole under expert guidance.

PROGNOSIS

Patients with paracoccidioidomycosis have an excellent response to antifungal therapy. Patients who have extensive pulmonary involvement at the time of diagnosis are at high risk for progressive fibrosis despite antifungal therapy.

CRYPTOCOCCOSIS

SHARON C-A CHEN

DEFINITION

Cryptococcosis occurs most often in persons who are immunosuppressed, especially individuals who are infected with human immunodeficiency virus (HIV; see Chapter 358). Meningoencephalitis is the most common clinical manifestation, but the lungs and other organs can be involved as well.[1]

The Pathogen

Cryptococcus neoformans and, much less often, *Cryptococcus gattii* are the predominant *Cryptococcus* species that cause infection in humans. In the environment, *Cryptococcus* species exist as yeasts that have minimal capsules and are easily aerosolized and inhaled. In human tissue, the yeasts are enveloped by a large polysaccharide capsule that is a major virulence factor. *C. neoformans* is found in the soil and grows well in avian droppings that have high nitrogen content.

EPIDEMIOLOGY

Before the widespread availability of antiretroviral therapy, cryptococcosis occurred in 5 to 10% of patients with acquired immunodeficiency syndrome (AIDS; Chapter 357), especially in patients whose CD4 counts were less than 50 cells/μL. Cryptococcosis is less commonly seen now in developed countries but remains very common in Africa,[2] where it is estimated that the prevalence among HIV-infected patients is as high as 30%.

C. neoformans is seen worldwide. *C. gattii* is more restricted geographically,[3] but its distribution has been increasing beyond Australia and Southeast Asia, where its ecologic niche is the eucalyptus tree, to Brazil, the Pacific Northwest, and other areas of North America. Other cryptococcal species rarely cause human disease.[4]

In the non-AIDS population, cryptococcosis is a frequent opportunistic infection in patients who have received a solid organ transplant, have been treated with corticosteroids or other immunosuppressive therapies, or have underlying illnesses, such as malignancy, diabetes mellitus, renal failure, cirrhosis, or chronic pulmonary disease. Rare cases have been transmitted from infected solid organ donors to organ recipients.[5] For some patients, the only risk factor appears to be older age, and approximately 20% of non-HIV patients who are infected with *C. neoformans* have no known underlying illness. By comparison, about 40 of cases of *C. gattii* are in apparently normal hosts.[6]

PATHOBIOLOGY

The organism is inhaled from the environment and initially causes pulmonary infection. The primary host defense at this stage is complement-dependent phagocytosis and killing by macrophages and neutrophils. Natural killer cells also have the ability to kill the organism. Ultimately, however, T-cell immunity is the most important host determinant in limiting the replication of *C. neoformans*. In most normal hosts, the infection remains localized to the lungs and does not cause symptomatic infection, but a few organisms likely exist as walled-off, subpleural granulomas in many individuals who have had pulmonary infection.

If the host becomes immunosuppressed, the organism can then reactivate and disseminate to other sites. *C. neoformans* is clearly neurotropic, and the primary disease manifestation is meningoencephalitis. However, dissemination to many organs is likely, especially in patients whose T-cell immunity is deficient.

Virulence factors for *C. neoformans* include the capsule, which requires opsonization for efficient phagocytosis, and the production of melanin, which enables the organism to resist intracellular killing. Both of these factors may help explain the virulence of the organism once it has reached the central nervous system (CNS). Antibody and complement levels are low in the brain, so phagocytosis of the organism is minimal. Brain tissue provides high concentrations of substrates, such as catecholamines, for the organism's phenol oxidase enzyme systems that produce melanin, thereby aiding its survival.

CLINICAL MANIFESTATIONS

Central Nervous System Infection

The most common manifestation of cryptococcosis is CNS infection, which typically is a subacute to chronic meningoencephalitis. Patients usually have

CRYPTOCOCCOSIS

SHARON C-A CHEN

DEFINITION

Cryptococcosis occurs most often in persons who are immunosuppressed, especially individuals who are infected with human immunodeficiency virus (HIV; see Chapter 358). Meningoencephalitis is the most common clinical manifestation, but the lungs and other organs can be involved as well.[1]

The Pathogen

Cryptococcus neoformans and, much less often, *Cryptococcus gattii* are the predominant *Cryptococcus* species that cause infection in humans. In the environment, *Cryptococcus* species exist as yeasts that have minimal capsules and are easily aerosolized and inhaled. In human tissue, the yeasts are enveloped by a large polysaccharide capsule that is a major virulence factor. *C. neoformans* is found in the soil and grows well in avian droppings that have high nitrogen content.

EPIDEMIOLOGY

Before the widespread availability of antiretroviral therapy, cryptococcosis occurred in 5 to 10% of patients with acquired immunodeficiency syndrome (AIDS; Chapter 357), especially in patients whose CD4 counts were less than 50 cells/μL. Cryptococcosis is less commonly seen now in developed countries but remains very common in Africa,[2] where it is estimated that the prevalence among HIV-infected patients is as high as 30%.

C. neoformans is seen worldwide. *C. gattii* is more restricted geographically,[3] but its distribution has been increasing beyond Australia and Southeast Asia, where its ecologic niche is the eucalyptus tree, to Brazil, the Pacific Northwest, and other areas of North America. Other cryptococcal species rarely cause human disease.[4]

In the non-AIDS population, cryptococcosis is a frequent opportunistic infection in patients who have received a solid organ transplant, have been treated with corticosteroids or other immunosuppressive therapies, or have underlying illnesses, such as malignancy, diabetes mellitus, renal failure, cirrhosis, or chronic pulmonary disease. Rare cases have been transmitted from infected solid organ donors to organ recipients.[5] For some patients, the only risk factor appears to be older age, and approximately 20% of non-HIV patients who are infected with *C. neoformans* have no known underlying illness. By comparison, about 40 of cases of *C. gattii* are in apparently normal hosts.[6]

PATHOBIOLOGY

The organism is inhaled from the environment and initially causes pulmonary infection. The primary host defense at this stage is complement-dependent phagocytosis and killing by macrophages and neutrophils. Natural killer cells also have the ability to kill the organism. Ultimately, however, T-cell immunity is the most important host determinant in limiting the replication of *C. neoformans*. In most normal hosts, the infection remains localized to the lungs and does not cause symptomatic infection, but a few organisms likely exist as walled-off, subpleural granulomas in many individuals who have had pulmonary infection.

If the host becomes immunosuppressed, the organism can then reactivate and disseminate to other sites. *C. neoformans* is clearly neurotropic, and the primary disease manifestation is meningoencephalitis. However, dissemination to many organs is likely, especially in patients whose T-cell immunity is deficient.

Virulence factors for *C. neoformans* include the capsule, which requires opsonization for efficient phagocytosis, and the production of melanin, which enables the organism to resist intracellular killing. Both of these factors may help explain the virulence of the organism once it has reached the central nervous system (CNS). Antibody and complement levels are low in the brain, so phagocytosis of the organism is minimal. Brain tissue provides high concentrations of substrates, such as catecholamines, for the organism's phenol oxidase enzyme systems that produce melanin, thereby aiding its survival.

CLINICAL MANIFESTATIONS

Central Nervous System Infection

The most common manifestation of cryptococcosis is CNS infection, which typically is a subacute to chronic meningoencephalitis. Patients usually have

ABSTRACT

Cryptococcosis is an opportunistic yeast infection that occurs mostly in patients who are immunosuppressed, especially individuals who have advanced HIV infection (AIDS). The two major species are *C. neoformans* and *C. gattii*. The latter is relatively restricted geographically, is less common, and occurs more often in immunocompetent individuals. Meningoencephalitis is the major manifestation of infection with *C. neoformans*. The portal of entry is the lungs, but pulmonary infection is often asymptomatic, so the patient presents for medical attention only after the organism has spread through the blood to the central nervous system. Less often, patients have isolated pulmonary infection. In patients with severe immunosuppression, the organism can disseminate to infect almost every organ system and often results in death. The cryptococcal antigen test is a sensitive and specific point-of-care test that can quickly identify patients with the infection. Treatment of meningitis and disseminated infection is with amphotericin B and flucytosine for 2 weeks, followed by fluconazole consolidation therapy for an additional 8 weeks and then suppressive therapy with fluconazole. The length of suppressive therapy depends on the patient's immunocompetence. Isolated pulmonary cryptococcosis is treated with oral fluconazole unless the patient is severely ill, in which case the initial therapy should be amphotericin B plus flucytosine.

increasingly severe headaches[7] over a period of several weeks, although some patients present over several days. Other symptoms and signs include nuchal rigidity, lethargy, personality changes, confusion, visual abnormalities (photophobia, diplopia, decreased visual acuity, papilledema, extraocular nerve palsies), nausea, and vomiting.[8] Less commonly, hearing loss, ataxia, and seizures occur. Fever is present in only approximately 50% of patients. Elderly persons with cryptococcal meningitis may present with cognitive impairment without other neurologic findings. AIDS patients often have subtle CNS symptoms but usually have fever and other constitutional symptoms, as well as rapidly developing signs of systemic dissemination.

Pulmonary Infection

In non–HIV-infected patients, the most common underlying risk factor for pulmonary cryptococcal infection[9] is chronic obstructive pulmonary disease (Chapter 76), followed by corticosteroid use and receipt of a solid organ transplant. *C. neoformans* may merely be an airway colonizer in some patients; in others, symptomatic infection, manifested by fever, cough, and dyspnea, requires treatment with an antifungal agent. The typical lesion noted with pulmonary cryptococcosis is a pleural-based nodule. However, patchy pneumonitis, multiple nodular lesions, cavitary lesions, mass-like lesions, and diffuse pulmonary infiltrates all have been noted with pulmonary cryptococcosis. Patients with advanced HIV infection are likely to have diffuse infiltrates that can progress rapidly to acute respiratory insufficiency (Chapter 90).

Involvement of Other Organs

C. neoformans can infect most organs during the course of disseminated infection, especially in AIDS patients (Chapter 358). Skin lesions are a prominent clue to dissemination, although isolated cutaneous cryptococcosis can occur in organ transplant recipients as well as in immunocompetent hosts. Papules that resemble molluscum contagiosum (Chapter 406) or an acneiform rash, nodules, ulcers, plaques, draining sinuses, and cellulitis all have been reported. Focal involvement can occur in the prostate and other organs of the genitourinary tract, in osteoarticular structures, in the breast, and in the eye, larynx, and other head and neck structures. The prostate, in particular, has been noted as a sanctuary from which persisting organisms can later disseminate.

DIAGNOSIS

The latex agglutination assay for cryptococcal polysaccharide antigen (CRAG) is a highly sensitive and specific diagnostic test. CRAG is positive in cerebrospinal fluid (CSF) in almost 100%[10] and in serum in about 75% of patients who have meningitis.[11] In AIDS patients, serum CRAG is almost always positive and is an excellent screening tool.[12] In these patients, titers in both CSF and serum are exceptionally high because of the enormous burden of organisms. In non-AIDS patients who have pulmonary cryptococcosis, the CRAG assay is positive in only 25 to 50% of cases. False-positive results with the CRAG assay are uncommon but have been reported in patients with *Trichosporon asahii* infections because of cross-reacting antigens shared by both fungi.

A point-of-care option is lateral flow analysis to detect cryptococcal polysaccharide antigen on a dipstick assay that can be performed in serum or CSF. This technique is as sensitive and specific as the classic CRAG test, including in isolated pulmonary infection.

The diagnosis of cryptococcosis is established when the yeast is grown in culture. Appropriate specimens for culture include CSF, blood, sputum, material from skin lesions, and other body fluids or tissues that appear to be infected. The organism grows in several days on most standard agar media. Most automated blood culture systems allow rapid growth of *C. neoformans* as well as *C. gattii*. Visualization of the capsule and performance of a few simple tests differentiate cryptococci from other yeasts. Tissue biopsy shows the 5- to 10-μm yeast surrounded by the capsule. Definitive diagnosis of cryptococcosis can be made by mucicarmine staining, which selectively stains the polysaccharide capsule a deep rose color. In CSF or other body fluids, an India ink preparation is useful in that it allows visualization of the budding yeast cells surrounded by the large capsule, but a negative test does not exclude a diagnosis of cryptococcosis (approximately 50% sensitivity in cryptococcal meningoencephalitis).

Lumbar Puncture

All immunosuppressed patients who have pulmonary cryptococcosis and all patients with any CNS symptoms should undergo lumbar puncture to be certain that meningitis is not present. Whether normal hosts with isolated pulmonary cryptococcosis and with negative serum antigen tests require lumbar puncture remains controversial.

The opening pressure on lumbar puncture may be elevated. The CSF of patients with cryptococcal meningitis typically has an increased number of white blood cells (but rarely >500/μL), a predominance of lymphocytes (although neutrophils are sometimes prominent early in the course), an elevated protein level, and a decreased glucose level. AIDS patients most often have normal or only mildly abnormal findings as a result of their markedly defective immune response. Every AIDS patient with a headache must have a CRAG or lateral flow analysis test and culture performed on their CSF, regardless of whether their CSF cell count, protein level, or glucose level is normal. Especially in AIDS patients, extremely high opening CSF pressure (>350 mm H_2O) has been associated with poor outcomes and must be aggressively lowered.

Imaging

All patients with cryptococcal meningitis should undergo computed tomography or magnetic resonance imaging of the brain to look for mass lesions and to assess ventricular size. Whether normal hosts with isolated pulmonary cryptococcosis require cerebral imaging should be considered in the context of the individual patient. Obstructive hydrocephalus is uncommon, and any increase in intracranial pressure is usually associated with normal-sized ventricles and is due to blockage at the arachnoid villi or increased brain edema (or both), perhaps related to the osmotic effect of the polysaccharide capsule.

TREATMENT

The treatment of cryptococcal infection requires appropriate antifungal therapy but also careful attention to local complications.[13]

Central Nervous System Infection

Antifungal Treatment

In the AIDS population, current recommendations are to give induction therapy with intravenous amphotericin B deoxycholate, 0.7 to 1 mg/kg daily, combined with oral flucytosine, 100 mg/kg daily given in four divided doses for at least 2 weeks, followed by consolidation therapy with oral fluconazole, 400 mg daily for a minimum of 8 weeks, and then suppressive therapy with fluconazole, 200 mg daily for 6 to 12 months. Lipid formulations of amphotericin B are increasingly used because they are less nephrotoxic, although they are often not available in developing countries. For example, single-dose liposomal amphotericin B (10 mg/kg) plus 14 days of flucytosine (100 mg/kg/day) and fluconazole (1200 mg/day) for 10 days is as good as a longer course of amphotericin.[A1] Induction therapy with amphotericin B (1 mg/kg per day for 4 weeks) plus flucytosine (100 mg/kg per day for 2 weeks) is also associated with improved survival among HIV-positive patients with cryptococcal meningitis compared with either amphotericin B alone or amphotericin B plus fluconazole (400 mg twice daily for 2 weeks).[A2] Unlike bacterial meningitis, adjunctive dexamethasone is not beneficial and appears to be detrimental in HIV-infected patients.

In non-AIDS patients, the course of treatment can be shorter. Antifungal therapy with a combination of amphotericin B and flucytosine for 6 weeks is preferred over amphotericin B alone for 10 weeks. High-dose fluconazole (800 mg/day) plus flucytosine may be another alternative.[14]

In HIV-positive patients, shorter regimens and regimens using amphotericin B with fluconazole or flucytosine with fluconazole[A3] are less effective but reasonable alternatives when the preferred regimen of amphotericin B plus flucytosine is not available. For example, 1 week of amphotericin B (1 mg per kilogram per day) plus flucytosine (100 mg per kilogram per day) and 2 weeks of fluconazole (1200 mg per day) plus flucytosine is effective as induction therapy[A4] and can be used to treat cryptococcal meningitis in resource-limited settings.

Case reports support the use of voriconazole and posaconazole (Chapter 307) for salvage treatment of cryptococcal meningitis. These are reasonable alternatives if no other azoles can be used. The echinocandins are not active against *C. neoformans* and should not be used.

Suppressive therapy with fluconazole is recommended for 6 to 12 months in transplant recipients. Suppressive therapy (e.g., fluconazole 200 mg daily) can be stopped in HIV patients who have undergone 12 months of antifungal therapy, who have $CD4^+$ counts higher than 100/μL, and whose HIV viral load is undetectable on antiretroviral therapy.

Increased Intracranial Pressure

Increased intracranial pressure, which is a cause of early death from cryptococcal meningitis, requires aggressive diagnosis and treatment in both AIDS and non-AIDS patients. Treatment to improve survival rates includes daily lumbar puncture or placement of a temporary lumbar drain or ventriculostomy until the opening pressure remains lower than 190 mm H_2O. Treatment with corticosteroids, acetazolamide, or mannitol has not proved efficacious.

Immune Reconstitution Syndrome

The development of immune reconstitution inflammatory syndrome (IRIS) can occur when patients with AIDS are receiving effective antiretroviral therapy that increases their CD4 count (Chapters 357 and 358).[15] Symptoms of meningitis reappear and are due to the inflammatory response, with an influx of CD4 lymphocytes and monocytes into the CSF and not to a relapse of disease. In HIV-positive patients who have cryptococcal meningitis and who have not previously received antiretroviral therapy, deferred antiretroviral therapy (5 weeks after diagnosis) is associated with significantly improved survival compared with earlier antiretroviral therapy (1 to 2 weeks after the diagnosis),[A5] especially among patients with a paucity of CSF white cells. IRIS can also occur in transplant recipients in whom immunosuppressive therapy is decreased rapidly. Generally, no specific therapy is needed for mild IRIS, but sometimes corticosteroids are needed under expert guidance if increased intracranial pressure occurs and/or if there is evidence of cerebral edema, even though they are otherwise unhelpful or even detrimental.

Pulmonary and Other Nonmeningeal Infections

Treatment of nonmeningeal cryptococcosis depends on the severity of the infection. Many patients with isolated pulmonary or other focal infections are not severely ill, and oral fluconazole, 400 mg daily for 6 to 12 months, is recommended. For patients who are severely ill, therapy is the same as noted earlier for CNS infection.

PREVENTION

Screening for cryptococcal antigen among HIV-positive patients with CD4 counts <200 cells/μL can detect presymptomatic diseases and guide early treatment.[16] In such patients, fluconazole, 200 mg three times per week, is safe and effective when used as primary prophylaxis, both before and during early antiretroviral treatment,[A6] but mortality may be as high as 25% even with early treatment.[17] By comparison, prophylactic treatment of asymptomatic HIV-positive individuals based on cryptococcal antigen screening has not been shown to be beneficial.[A7]

PROGNOSIS

The outcome for both AIDS and non-AIDS patients with cryptococcal meningitis has improved markedly in the developed world.[18] In one U.S. series of HIV-positive patients with cryptococcal infection (about 70% with meningitis), early mortality was only 17% but more than 50% of patients died by about 42 months.[19] In Africa, however, the mortality from cryptococcal meningitis in AIDS patients approaches 100% in some areas because of lack of access to specific therapy. Among patients with HIV, a predominant T_H1 cytokine profile in the CSF and blood at diagnosis appears to predict a better survival.

Even in non-AIDS patients in the United States, outcomes typically include substantial neurologic abnormalities.[20] Dementia, which usually occurs in older patients, hearing loss, and visual loss may not be reversed even though mycologic cure is achieved.

310 CANDIDIASIS

PETER G. PAPPAS

DEFINITION

Candidiasis encompasses a wide variety of clinical syndromes caused by yeasts of the genus *Candida*. Of the species that cause infection in humans, *Candida albicans* is the most common; *Candida glabrata, Candida parapsilosis*, and *Candida tropicalis* are responsible for most of the remaining infections, but *Candida auris* has emerged as a major pathogen in some parts of the world.[1] Organisms such as *Candida krusei, Candida lusitaniae*, and *Candida guilliermondii* are less common causes of infection.

The Pathogen

Candida species are 2- to 6-μm yeastlike organisms that reproduce by budding. Most species, with the exception of *C. glabrata*, form pseudohyphae (elongated buds that remain attached to the mother cell) and hyphae in tissues.

Candida species cause a wide spectrum of diseases ranging in severity from localized mucous membrane infection to life-threatening disseminated disease. The major determinant of the severity of infection is the host's immune response. Local infections are often related to overgrowth of *Candida* as a result of changes in the normal microbiota. Invasive infections that remain within an organ system, such as urinary tract infections, usually occur because of local anatomic abnormalities. In an immunosuppressed host, especially a patient with neutropenia, widespread visceral dissemination is common.

EPIDEMIOLOGY

C. albicans is the species most commonly found colonizing humans; *C. glabrata* is the second most common species, and *C. tropicalis, C. parapsilosis*, and others are found less often. *C. glabrata*, a species that is increasingly resistant to fluconazole, has become a prominent pathogen in many hospitals. In many parts of the world, *C. auris*, a previously uncommon multidrug-resistant *Candida* species, has caused outbreaks and created new challenges in understanding the epidemiology, treatment, and prevention of this organism.

Though uncommon, acquisition of *Candida* from environmental sources has been noted. The *Candida* species most often associated with transmission from contaminated fluids or devices, especially central intravenous catheters, is *C. parapsilosis*.

Candidiasis is the most common opportunistic fungal infection as a result of both the organisms' ubiquity and the increasing number of patients who have risk factors for infection with these organisms.[2] The classic immunosuppressed host at risk for serious *Candida* infections is a neutropenic patient who has a hematologic malignancy and who has received cytotoxic agents and corticosteroids. Candidiasis is increasingly being seen in patients who are in intensive care units (ICUs). Risk factors for the development of serious *Candida* infections in ICU patients include diabetes,[3] the use of broad-spectrum antimicrobial agents, indwelling central venous catheters, intravenous drug use (Chapter 365),[4] previous surgical procedures, renal failure, parenteral nutrition, pancreatitis, dialysis, and a high Acute Physiology and Chronic Health Evaluation (APACHE) score. Certain ICU populations, especially burn victims (Chapter 97), are at even higher risk for *Candida* infection than is the typical ICU patient.[5]

The primary manifestation of *Candida* infection in patients with HIV/AIDS (Chapter 358) is mucocutaneous infection, primarily oropharyngeal candidiasis. The development of mucosal *Candida* infection is related to deficient T-cell immunity as reflected by a low CD4 lymphocyte count. With current antiretroviral therapy, oropharyngeal and esophageal candidiasis are much less common.

PATHOBIOLOGY

The usual mode of infection with *Candida* is egress from its normal niche into the bloodstream or other tissues; the source is usually the gastrointestinal tract, but the skin and genitourinary tract are other sources. The primary host defense in response to this event is phagocytosis and killing by neutrophils, monocytes, and macrophages. C-C chemokine receptor 2 (CCR2)-expressing inflammatory monocytes and their tissue-resident derivatives play

Immune Reconstitution Syndrome

The development of immune reconstitution inflammatory syndrome (IRIS) can occur when patients with AIDS are receiving effective antiretroviral therapy that increases their CD4 count (Chapters 357 and 358).[15] Symptoms of meningitis reappear and are due to the inflammatory response, with an influx of CD4 lymphocytes and monocytes into the CSF and not to a relapse of disease. In HIV-positive patients who have cryptococcal meningitis and who have not previously received antiretroviral therapy, deferred antiretroviral therapy (5 weeks after diagnosis) is associated with significantly improved survival compared with earlier antiretroviral therapy (1 to 2 weeks after the diagnosis),[A5] especially among patients with a paucity of CSF white cells. IRIS can also occur in transplant recipients in whom immunosuppressive therapy is decreased rapidly. Generally, no specific therapy is needed for mild IRIS, but sometimes corticosteroids are needed under expert guidance if increased intracranial pressure occurs and/or if there is evidence of cerebral edema, even though they are otherwise unhelpful or even detrimental.

Pulmonary and Other Nonmeningeal Infections

Treatment of nonmeningeal cryptococcosis depends on the severity of the infection. Many patients with isolated pulmonary or other focal infections are not severely ill, and oral fluconazole, 400 mg daily for 6 to 12 months, is recommended. For patients who are severely ill, therapy is the same as noted earlier for CNS infection.

PREVENTION

Screening for cryptococcal antigen among HIV-positive patients with CD4 counts <200 cells/μL can detect presymptomatic diseases and guide early treatment.[16] In such patients, fluconazole, 200 mg three times per week, is safe and effective when used as primary prophylaxis, both before and during early antiretroviral treatment,[A6] but mortality may be as high as 25% even with early treatment.[17] By comparison, prophylactic treatment of asymptomatic HIV-positive individuals based on cryptococcal antigen screening has not been shown to be beneficial.[A7]

PROGNOSIS

The outcome for both AIDS and non-AIDS patients with cryptococcal meningitis has improved markedly in the developed world.[18] In one U.S. series of HIV-positive patients with cryptococcal infection (about 70% with meningitis), early mortality was only 17% but more than 50% of patients died by about 42 months.[19] In Africa, however, the mortality from cryptococcal meningitis in AIDS patients approaches 100% in some areas because of lack of access to specific therapy. Among patients with HIV, a predominant T_H1 cytokine profile in the CSF and blood at diagnosis appears to predict a better survival.

Even in non-AIDS patients in the United States, outcomes typically include substantial neurologic abnormalities.[20] Dementia, which usually occurs in older patients, hearing loss, and visual loss may not be reversed even though mycologic cure is achieved.

Candidiasis is increasingly being seen in patients who are in intensive care units (ICUs). Risk factors for the development of serious *Candida* infections in ICU patients include diabetes,[3] the use of broad-spectrum antimicrobial agents, indwelling central venous catheters, intravenous drug use (Chapter 365),[4] previous surgical procedures, renal failure, parenteral nutrition, pancreatitis, dialysis, and a high Acute Physiology and Chronic Health Evaluation (APACHE) score. Certain ICU populations, especially burn victims (Chapter 97), are at even higher risk for *Candida* infection than is the typical ICU patient.[5]

The primary manifestation of *Candida* infection in patients with HIV/AIDS (Chapter 358) is mucocutaneous infection, primarily oropharyngeal candidiasis. The development of mucosal *Candida* infection is related to deficient T-cell immunity as reflected by a low CD4 lymphocyte count. With current antiretroviral therapy, oropharyngeal and esophageal candidiasis are much less common.

PATHOBIOLOGY

The usual mode of infection with *Candida* is egress from its normal niche into the bloodstream or other tissues; the source is usually the gastrointestinal tract, but the skin and genitourinary tract are other sources. The primary host defense in response to this event is phagocytosis and killing by neutrophils, monocytes, and macrophages. C-C chemokine receptor 2 (CCR2)-expressing inflammatory monocytes and their tissue-resident derivatives play

ABSTRACT

Candida species reside in the gastrointestinal and genitourinary tracts and on the skin of humans. The species that is most commonly encountered as a cause of infection is *Candida albicans*, but in some medical centers, *C. glabrata, C tropicalis, C. parapsilosis,* and *C auris* also are major pathogens. Infections caused by *Candida* species vary from benign localized mucous membrane infections to focal invasive infections to disseminated infections with a high mortality rate. Examples of mucous membrane infections are oropharyngeal candidiasis, esophagitis, and vulvovaginitis. These infections are generally treated with oral fluconazole. Focal invasive infections include urinary tract infections, osteoarticular infections, meningitis, and endophthalmitis. Urinary tract infections can be treated with fluconazole in most patients, but endophthalmitis, meningitis, and osteoarticular infections are more complicated, must be treated with longer courses of therapy, and for some patients will require initial treatment with another agent, such as amphotericin B. Candidemia and non–central nervous system invasive candidiasis should be treated initially with an echinocandin; transition to oral fluconazole after the patient has responded to initial intravenous therapy is reasonable if the *Candida* species causing the infection is susceptible.

KEYWORDS

Candida
candidemia

echinocandin

an essential antifungal role, particularly in the first 48 hours after *Candida* infection. Phagocytosis is enhanced in the presence of specific anti-*Candida* antibody and complement. Several different mechanisms are operative within neutrophils and macrophages that allow the killing of yeasts. Thus, patients who are leukopenic (Chapter 153), especially those with chemotherapy-induced disruption of the gut mucosa, are at great risk for invasion with *Candida* species. Once *Candida* gains access to the bloodstream, widespread hematogenous dissemination is the rule. Biopsy of involved organs shows multiple microabscesses composed of neutrophils (in a host who has these cells), budding yeasts, and often pseudohyphae or hyphae. Over time, the lesions show a mixed neutrophilic and granulomatous response.

T-cell immunity is an important host defense against infection with *Candida* at mucosal surfaces. In contrast to patients with neutropenia, patients with deficient T-cell immunity are at risk for persistent and recurrent mucocutaneous candidiasis, but invasive infection rarely develops.

CLINICAL MANIFESTATIONS

Mucocutaneous Candidiasis

Oropharyngeal Candidiasis

Local mucous membrane and cutaneous lesions are the most common forms of *Candida* infection.[6] Oropharyngeal candidiasis, or *thrush* (Chapter 393), can be due to either local factors or T-cell dysfunction. Local factors include the use of broad-spectrum antimicrobial agents, inhaled corticosteroids, xerostomia (Chapter 393), and radiation treatment of the head and neck. Denture stomatitis occurs frequently in persons who wear full upper dentures, especially individuals who do not remove their dentures at night.

Thrush secondary to T-cell dysfunction is most commonly seen in patients with HIV infection (Chapter 358) and is the most frequent opportunistic infection noted in patients with AIDS. The appearance of thrush in a previously healthy individual with no known risk factors should immediately raise suspicion of HIV infection.

Thrush manifests with white plaques on the buccal mucosa, palate, oropharynx, or tongue (Fig. 310-1). Scraping the lesions with a tongue depressor reveals an erythematous, nonulcerated mucosa under the plaques. Denture stomatitis almost always manifests as a painful erythematous palate without plaques. Angular cheilitis, or perlàche, which is the presence of painful cracks at the corners of the mouth, can occur with or without thrush.

Esophagitis

Esophagitis may accompany oropharyngeal candidiasis or may occur independently of lesions in the oropharynx (Chapter 124). The development of *Candida* esophagitis is almost always related to immune dysfunction and not simply to local factors.[7] *Candida* esophagitis occurs in patients with AIDS and low CD4 counts, patients with leukemia, and patients who are taking immunosuppressive agents. *Candida* esophagitis occurs rarely in otherwise normal hosts. The classic symptom of *Candida* esophagitis is odynophagia localized to a discrete substernal area. The differential diagnosis includes ulcerations due to herpes simplex or cytomegalovirus and, in patients with AIDS, idiopathic ulcers.

Vulvovaginitis

Candida vulvovaginitis is a common infection in women of childbearing age and is the most frequent mucocutaneous manifestation of *Candida* infection.

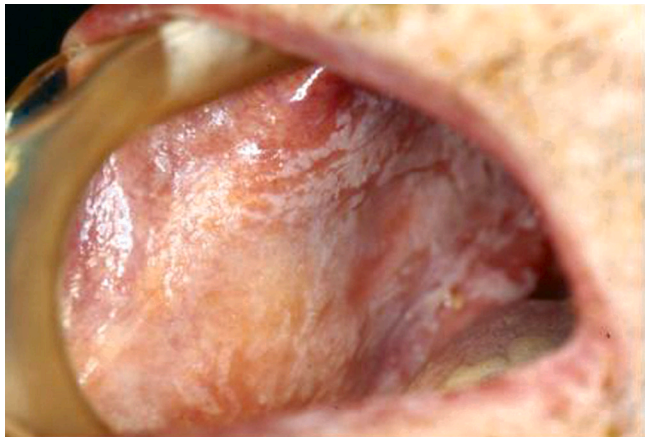

FIGURE 310-1. Thrush.

Risk factors include conditions associated with increased estrogen levels, such as the use of oral contraceptives and pregnancy, diabetes mellitus, therapy with corticosteroids or broad-spectrum antimicrobials, and HIV infection. Symptoms include vaginal discomfort, discharge, and vulvar pruritus.[8] The discharge is usually curdlike, but it can also be thin and watery. The labia are erythematous and swollen, and the vaginal walls show erythema and white plaques. Although most women have only a few episodes throughout their lives, a minority have frequent recurrences; in most of these patients, no discrete risk factor can be identified, and the cause is presumed to be local immune dysregulation.

Cutaneous Candidiasis

Candida infection of the skin (Chapter 405) occurs mostly in the intertriginous areas or under a large pannus or pendulous breasts. The lesions, which are erythematous, pruritic, and frequently pustular, have a distinct border and are almost always associated with smaller satellite lesions, which help distinguish candidiasis from tinea cruris or corporis. *Candida* onychomycosis results in thickened, opaque, and onycholytic nails (Chapter 409). *Candida* can also cause paronychia, especially in patients whose occupation involves frequent immersion of the hands in water.

Chronic Mucocutaneous Candidiasis

Chronic mucocutaneous candidiasis is an uncommon syndrome that usually begins in childhood and is characterized by recalcitrant and relapsing thrush, esophagitis, vaginitis, onychomycosis, and hyperkeratotic skin lesions on the face, scalp, and hands. Autosomal dominant chronic mucocutaneous candidiasis is associated with mutations in the CC domain of *STAT1*, thereby leading to defective T_H1 and T_H17 responses. Some patients have associated autoimmune endocrinopathies, including hypoparathyroidism, hypothyroidism, and hypoadrenalism (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED]), which is caused by a loss-of-function mutation of the autoimmune regulator gene, *AIRE*; in these patients autoantibodies against interleukin-17 (IL-17) and IL-22 are found (Chapter 212).

Disseminated Infections

Candidemia

The most common manifestation of disseminated *Candida* infection is candidemia.[9] However, candidemia merely implies the presence of *Candida* in blood; it does not define the extent of visceral involvement. *Candida* obtained from a blood culture should never be considered a contaminant and should always prompt a search for the probable source and the extent of infection. Risk factors for candidemia include broad-spectrum antimicrobial therapy, central intravenous catheters, parenteral nutrition (Chapter 198), renal failure, pancreatitis (Chapter 130), any type of dialysis (Chapter 117), surgical procedures involving the gastrointestinal tract, neutropenia, and corticosteroid therapy (Chapter 28).[10] The attributable mortality from among all patients with candidemia approaches 40%. Mortality is higher in elderly patients and among patients with severe sepsis (Chapter 94) and poor control of the infectious source.

Although candidemia is the most obvious manifestation of serious infection with *Candida* species, septic shock (Chapter 94) can occur and be accompanied by invasion of multiple viscera even in the absence of positive blood cultures. The clinical picture of invasive candidiasis is indistinguishable from that of bacterial infection. The characteristic histologic picture consists of multiple microabscesses in many organs. The eyes, kidneys, liver, spleen, and brain are the most commonly involved sites, but virtually all organs can be involved. Clinical clues to the diagnosis of invasive candidiasis include the appearance of skin and retinal lesions. The nonpainful, nonpruritic skin lesions are papular to pustular and surrounded by a zone of erythema (Fig. 310-2). Classical eye lesions appear as distinctive white exudates in the retina (Fig. 310-3); with extension into the vitreous body, the retina becomes obscured.

Endocarditis

Candida endocarditis (Chapter 61), which is an uncommon and often fatal complication of candidemia, occurs most often on native valves among intravenous drug users and in patients who have prosthetic cardiac valves or indwelling intravascular devices.[11] Blood cultures are usually persistently positive, and echocardiography reveals large vegetations that can readily embolize to major vessels.

Chronic Disseminated (Hepatosplenic) Candidiasis

Disseminated hepatosplenic candidiasis almost always occurs in leukemic patients who have had an episode of neutropenia. After the neutrophil count

FIGURE 310-2. Skin lesions in invasive candidiasis.

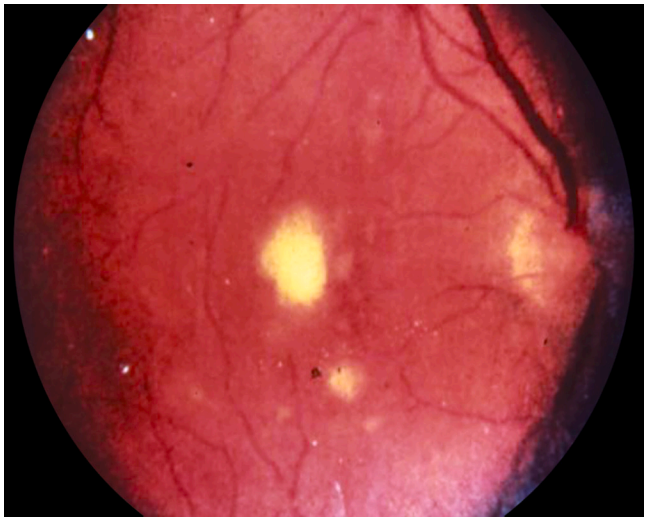

FIGURE 310-3. Retinal involvement.

returns to normal, fevers that are often quite high, right upper quadrant tenderness, and nausea develop. The alkaline phosphatase level is generally elevated, and distinctive punched-out lesions are seen in the liver, spleen, and sometimes the kidneys on computed tomography (Fig. 310-4). Biopsy of these lesions shows microabscesses that may contain budding yeasts.

Focal Invasive Infections

Focal invasive candidiasis infections result from local inoculation, contiguous spread, or hematogenous spread. Hematogenous spread, which often goes undetected, is probably the most common pathogenetic mechanism.

Urinary Tract Infections

Candiduria, which is a frequent finding in hospitalized patients, is related to factors such as diabetes mellitus, broad-spectrum antimicrobial treatment, indwelling urinary devices, and genitourinary tract structural abnormalities. Most patients with candiduria have only bladder colonization and not true infection. Urinary tract infection with *Candida* species can arise by two mechanisms. Patients with candidemia can develop multiple microabscesses secondary to hematogenous spread to the kidneys. Other patients, who have the risk factors noted earlier, can develop cystitis or ascending infection with pyelonephritis. Patients with cystitis or pyelonephritis have symptoms indistinguishable from those of bacterial infections (Chapter 263). A fungus ball composed of fungal hyphae can develop at any level of the collecting system and lead to obstruction, with subsequent infection.

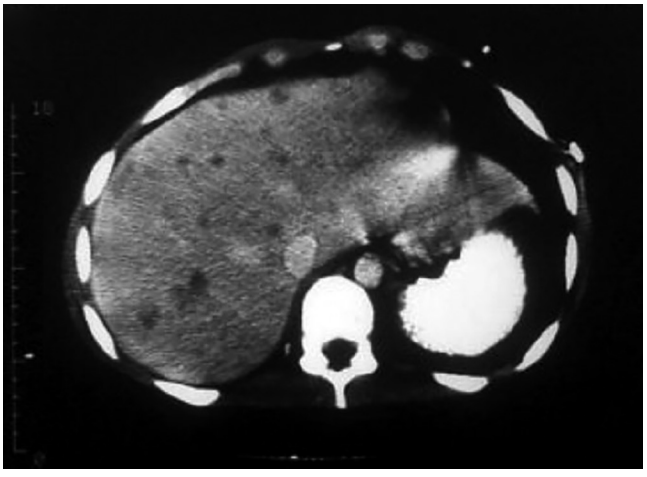

FIGURE 310-4. Computed tomography scan of a patient with chronic disseminated candidiasis (hepatosplenic candidiasis). Note the distinctive punched-out lesions in the liver.

Osteoarticular Infections

Osteoarticular infections arise secondary to hematogenous seeding or exogenous inoculation during intra-articular injection, a surgical procedure, or trauma. Vertebral osteomyelitis (Chapter 251) is the most common manifestation of osteoarticular candidiasis. The symptoms of back pain and fever may occur many weeks after an episode of fungemia.

Endophthalmitis

Exogenous endophthalmitis (Chapter 391) occurs secondary to trauma or ophthalmic surgery. Most often, the procedure involved is cataract extraction, with or without lens implantation, and the most common infecting species is *C. parapsilosis*. Primary infection occurs in the anterior chamber, but ultimately the posterior chamber is also involved. Endogenous *Candida* endophthalmitis, which results from hematogenous seeding of the choroid and retina, is one of the most serious complications of candidemia. Characteristic white lesions are visible in the retina. With progression of the infection, vitritis occurs, and the risk for loss of vision is quite high.

Peritonitis

Candida peritonitis can follow bowel surgery or perforation. Symptoms are the same as those noted in bacterial peritonitis (Chapter 128). Usually, this type of infection is polymicrobial, and abscess formation is common. In patients maintained on continuous ambulatory peritoneal dialysis (Chapter 117), *Candida* peritonitis generally develops as a late infection after previous episodes of bacterial peritonitis. A cloudy dialysate, abdominal pain, and fever are typically noted.

Meningitis

Acute *Candida* meningitis occurs as part of disseminated infection, especially in low-birthweight neonates. Chronic meningitis, an uncommon manifestation of candidiasis, resembles cryptococcal or tuberculous meningitis with regard to symptoms and cerebrospinal fluid findings. Foreign body–associated meningitis (e.g., an infected ventriculoperitoneal shunt, or Ommaya reservoir) clinically more closely resembles bacterial meningitis.

DIAGNOSIS

Mucocutaneous Candidiasis

The diagnosis of mucocutaneous candidiasis is often made clinically. Culture is rarely indicated. Confirmation can be sought by scraping the lesions and performing either a potassium hydroxide preparation or a Gram stain to look for budding yeasts (Chapter 403). If the lesions are recurrent or unresponsive to standard therapy, they should be cultured to establish whether a more resistant species, such as *C. glabrata* or *C. krusei*, is the causative agent. In the event of suspected esophagitis, endoscopy shows plaquelike lesions or

ulcerations (Fig. 124-13), and biopsy shows mucosal invasion with budding yeasts and pseudohyphae.

Invasive Candidiasis

The diagnosis of invasive candidiasis is more difficult. Blood cultures are not sensitive enough for clinicians to rely on them to establish the diagnosis of invasive candidiasis in all cases or to exclude candidiasis as a diagnostic possibility. In addition, 1 to 4 days are required for growth to occur; in a desperately ill patient, this delay is problematic. As a result, non–culture-based techniques are increasingly used to aid in the diagnosis of invasive candidiasis,[12] including β-D-glucan, which is a cell wall component of many fungi, including *Candida* species.[13] The β-D-glucan assay is not specific for *Candida* infections, but it has moderately good sensitivity in patients who are at high risk for invasive candidiasis. Polymerase chain reaction (PCR) testing is not standardized, but some studies show that it is more sensitive than β-D-glucan and blood cultures. A rapid technique testing whole blood samples to identify *Candida* species by use of magnetic biosensor technology is coming into broader use in North America and Europe.[14]

The tips of intravenous catheters that have been removed should be sent for culture. However, no studies have evaluated the number of yeasts that is indicative of infection, and many physicians accept the growth of any yeast as affirming infection that requires treatment. Many focal forms of candidiasis are indistinguishable from bacterial infection, and biopsy should be performed for histopathologic and culture studies.

In a seriously ill patient suspected of having candidiasis, the development of pustular skin lesions or typical retinal lesions can be helpful. Budding yeasts typical of *Candida* species should be sought by smearing material from a pustule on a slide and staining it with Gram stain or by performing a biopsy of a lesion and staining the tissue section with a silver stain. All patients who are candidemic or suspected of having disseminated *Candida* infection should undergo a dilated ophthalmologic examination by an experienced examiner or an ophthalmologist to look for typical retinal lesions.

Imaging studies are invaluable for certain forms of candidiasis, especially chronic disseminated candidiasis, and they can be of major help in defining the extent of infection in other types of *Candida* infection, such as osteoarticular and urinary tract infections and endocarditis.

TREATMENT

Mucocutaneous disease is treated much differently than disseminated, life-threatening infection. Because diagnostic tests are not sensitive, empirical therapy is indicated in some circumstances, and antifungal prophylaxis can decrease the risk for *Candida* infection in highest-risk patients (see later under Prevention).

Mucocutaneous Infections

Most mucocutaneous infections should initially be treated with local creams, solutions, troches, or suspensions. For thrush, clotrimazole troches (10 mg four or five times daily for 7 to 14 days) are preferred to nystatin suspension (commonly given as "swish and swallow" four times daily). Patients with AIDS may not respond to local therapy, especially when their CD4 counts are low; in this situation, oral fluconazole (100 to 200 mg daily for 7 to 14 days) is given.[A1] For vulvovaginal candidiasis, a variety of creams and vaginal tablets (miconazole, clotrimazole, and others) are effective, but many women prefer to take a single 150-mg fluconazole tablet orally.[15] Ibrexafungerp (300 mg twice daily for 1 day) is another alternative.[A2] Recurrent vaginitis, which is a more complicated therapeutic issue, often requires chronic suppressive therapy with fluconazole. Esophagitis should always be treated with a systemically absorbed agent; the usual treatment is fluconazole 200 mg/day for 14 days.[16]

In patients with advanced AIDS and low CD4 counts, who are often taking fluconazole to prevent recurrent candidiasis, fluconazole-refractory disease may develop. For these patients, increasing the dosage of fluconazole or switching to itraconazole suspension 200 mg daily, voriconazole 200 mg twice daily, or posaconazole suspension 400 mg or extended-release tablets 300 mg, each given once daily, should be effective. If oral tablets and solutions are no longer effective, intravenous amphotericin B (0.3 to 0.7 mg/kg daily), caspofungin (50 mg daily), anidulafungin (200 mg daily), or micafungin (100 mg daily) for 14 to 21 days are alternatives. Patients with the syndrome of chronic mucocutaneous candidiasis require lifelong suppressive therapy with oral azole agents (e.g., fluconazole 200 to 400 mg daily). More recent alternatives, ibrexafungerp (300 mg twice daily) and oteseconazole (600 mg day 1, 450 mg day 2, then 150 mg weekly for 2 to 12 weeks), may play a role in the treatment of drug-resistant mucosal infections (ibrexafungerp), as well as in the treatment and prevention of recurrent vulvovaginal candidiasis (oteseconazole).[17]

Candidemia and Invasive Candidiasis

Culture-Positive Patients

All patients with candidemia should be treated with an antifungal agent, including patients who have only one blood culture that yields *Candida*. The rationale for this recommendation is related to the high rate of metastatic foci in major organs associated with hematogenously disseminated candidiasis. Vascular catheters should be removed if at all feasible because removal has been shown to help clear *Candida* from blood more quickly.

Randomized controlled trials have documented the effectiveness of the following antifungal agents for the treatment of candidemia: fluconazole (400 or 800 mg/day); the three echinocandins (caspofungin 50 mg/day, anidulafungin 100 mg/day, and micafungin 100 mg/day)[A3,A4]; voriconazole (3 mg/kg twice daily); amphotericin B (0.7 mg/kg/day); and a lipid formulation of amphotericin B (3 to 5 mg/kg/day). Current guidelines recommend an echinocandin (caspofungin, micafungin, or anidulafungin; see earlier) as initial therapy in both neutropenic and non-neutropenic patients. Fluconazole is an acceptable alternative, but only for patients who are not severely ill and who are considered unlikely to have an azole-resistant *Candida* species. Isavuconazole is not as efficacious as caspofungin[A5] and is not approved for candidemia. Patients who have stabilized clinically and are found to have an isolate, such as *C. albicans*, that is likely to be susceptible to fluconazole can be transitioned to fluconazole from an echinocandin. Voriconazole can be used for step-down therapy if the organism is susceptible, but it offers little advantage over fluconazole. Amphotericin B formulations are used infrequently, except for patients who are neutropenic and for neonates.

Repeated blood cultures should be obtained to ascertain that the fungemia has resolved, and treatment should continue for at least 2 weeks after the date of the first negative blood culture.[18]

Empiric Treatment

Because diagnostic tests are not sensitive, seriously ill patients who could have invasive candidiasis may need to be treated before culture confirmation. This approach is used frequently in neutropenic patients, in whom empiric liposomal amphotericin B, caspofungin, and voriconazole have been shown in randomized clinical treatment trials to be effective. In the ICU setting, empiric antifungal treatment is often used, but empiric fluconazole therapy has failed to show a benefit, and the overall value of this approach is less certain.[19] Current guidelines recommend that empiric therapy be reserved for febrile, critically ill patients who have risk factors for invasive candidiasis. The preferred treatment is an echinocandin (caspofungin, micafungin, or anidulafungin). In non-neutropenic, nontransplanted, critically ill patients who have ICU-acquired sepsis, *Candida* colonization, and multiorgan failure while taking broad-spectrum antibiotics, empirical micafungin (100 mg daily for 14 days) can decrease the rate of new invasive fungal infection but does not increase fungal-free survival at day 28.[A6]

Endocarditis should be treated with a lipid formulation of amphotericin B (3 to 5 mg/kg/day for 6 weeks), with or without flucytosine (25 mg/kg four times daily). An echinocandin (e.g., caspofungin 70 mg, micafungin 150 mg, or anidulafungin 200 mg) given daily is an acceptable alternative. Infected valves should be replaced. In a few patients for whom valve replacement was not an option, lifelong suppression with fluconazole (400 to 800 mg daily) may be effective.

Chronic disseminated candidiasis generally requires months of therapy for cure. Most patients begin therapy with a lipid formulation of amphotericin B (3 to 5 mg/kg/day) or an echinocandin (e.g., caspofungin 50 mg, micafungin 100 mg, or caspofungin 50 mg daily) for 14 days and are then switched to fluconazole (400 to 800 mg) daily for several weeks to months and treated until the lesions disappear on computed tomographic scanning. This process of radiographic resolution may require several months.

Focal Invasive Infections

Treatment of focal infections depends on the organ system involved. Perhaps the simplest to treat are urinary tract infections. Most patients with candiduria are not infected but merely colonized; removing the selective pressure of antimicrobials and indwelling catheters eliminates candiduria in many of these patients. For those who have infection, oral fluconazole (200 mg/day orally for 2 weeks) is recommended. Bladder irrigation with amphotericin B (50 mg/L saline for 5 days) can be used for resistant *Candida* species (e.g., fluconazole-resistant *C. glabrata* or *C. krusei*), but this treatment eradicates only bladder colonization, requires that a catheter be placed in the bladder, and is associated with a high recurrence rate. None of the newer antifungal agents has a proven role in the treatment of urinary tract infections.

Osteoarticular infections require months of therapy; a lipid formulation of amphotericin B (3 to 5 mg/kg/day) or an echinocandin (e.g., caspofungin 50 mg, micafungin 100 mg, or anidulafungin 100 mg daily) can be given initially for at least 2 weeks, followed by long-term therapy with fluconazole (400 mg daily) for at least 6 months. Peritonitis associated with chronic ambulatory peritoneal dialysis can be treated with amphotericin B (3 to 5 mg/kg/day), fluconazole (400 mg daily), or a daily echinocandin (e.g., caspofungin 50 mg/day, micafungin 100 mg/day, or anidulafungin 100 mg), depending on the species of *Candida* causing infection, for 7 to 14 days. Intraperitoneal administration of amphotericin B can be extremely irritating and should generally be avoided. The dialysis catheter should be removed. Meningitis should be treated initially with a lipid formulation of amphotericin B (5 mg/kg/day) and flucytosine (25 mg/kg

four times daily) for at least 14 days; patients with more chronic disease can be switched to fluconazole (400 to 800 mg daily) for a longer duration of therapy, typically for several weeks.

Treatment of *Candida* eye infections varies with the extent of ocular involvement. Lesions discovered early at the stage of choroidal or retinal involvement can be treated effectively with intravenous amphotericin B (3 to 5 mg/kg), an echinocandin (e.g., caspofungin 50 mg daily, micafungin 100 mg daily, or anidulafungin 100 mg daily), fluconazole (400 mg daily), or voriconazole (200 mg twice daily) for at least 2 weeks after the first negative blood culture. Many experts prefer to use an agent, such as voriconazole or fluconazole, that achieves higher concentrations in the eye. Lesions extending into the vitreous require more aggressive therapy. The best results have been obtained with pars plana vitrectomy, injection of amphotericin B or voriconazole into the vitreous, and a systemic antifungal agent such as fluconazole (400 mg daily) or voriconazole (200 mg twice daily) for several weeks. Management must be individualized and performed in concert with an ophthalmologist experienced in the treatment of this infection. Treatment of endophthalmitis associated with an intraocular lens implant requires removal of the implant, vitrectomy and local amphotericin B injections, as well as therapy with fluconazole or voriconazole.

PREVENTION

For patients at the highest risk for invasive candidiasis and other fungal infections, prophylactic antifungal agents can prevent infection. The populations for whom prophylaxis is recommended include stem cell transplant recipients (Chapter 163), patients with acute leukemia who are undergoing induction chemotherapy (Chapter 168), high-risk liver transplant recipients (Chapter 140), and pancreas and small bowel transplant recipients. In these groups, a variety of different agents are effective. In the ICU population, prophylaxis with fluconazole (400 mg daily) can be effective, but it is recommended only in units that have a high rate of invasive candidiasis, and only in patients at the highest risk for infection. For example, using caspofungin (50 mg daily) as antifungal prophylaxis in adults who were in the ICU for at least 3 days, were ventilated, received antibiotics, had a central line, and had at least one additional risk factor was safe and reduced the incidence of invasive candidiasis in one randomized trial, but the benefit was not statistically significant.[A7] Restricting the use of prophylaxis to individuals at higher risk for candidiasis is essential to prevent the widespread use of azoles, with subsequent selection of resistant species. An experimental vaccine has shown promise in reducing recurrent symptomatic vulvovaginal candidiasis.[A8]

PROGNOSIS

The prognosis for patients with mucocutaneous infections is excellent. The prognosis for focal invasive infections depends on the organ involved and the patient's immune status. For example, whereas pyelonephritis may respond well to antifungal therapy, endocarditis and meningitis are more difficult to treat and have poor outcomes.

For invasive candidiasis, overall mortality is about 30 to 40%.[20] Significant predictors of mortality include increasing age, use of immunosuppressive therapy, and infection with *C. tropicalis*. Improved survival and clinical success are associated with early treatment with an effective antifungal agent, the use of an echinocandin, and the removal of central venous catheters. In candidemic patients who have septic shock, mortality rates as high as 98% are seen in patients in whom antifungal therapy and effective source control (i.e., draining abscesses and removing central venous catheters) is delayed beyond 24 hours after the onset of shock.

311 ASPERGILLOSIS

THOMAS J. WALSH AND THOMAS F. PATTERSON

DEFINITION

Aspergillosis is a disease caused by one or more of the species of the genus *Aspergillus*. Sporelike structures called *conidia* are aerosolized from the mold form of the organism growing in the environment. When conidia reach tissue, they germinate to form invasive filaments called *hyphae*.

The Pathogens

The most common species infecting humans are *Aspergillus fumigatus, Aspergillus flavus, Aspergillus terreus*, and *Aspergillus niger. Aspergillus* species are usually identified in culture by characteristic microscopic features of hyphae and the structures producing conidia. When some species are not readily identifiable, they may be reported by the clinical laboratory as "*Aspergillus* species" or "*Aspergillus* sp." *A. fumigatus* may be reported as "*A. fumigatus* species complex." *A. terreus* is resistant to amphotericin B. Aspergilli within tissue appear as dichotomously branched (Y-shaped) septate hyphae. *Scedosporium* and *Fusarium* species also may produce septate hyphae in tissue. The presence of septa and dichotomous branching differentiates *Aspergillus* species from the Mucorales, which are the causative organisms of mucormycosis (Chapter 312).

EPIDEMIOLOGY

Aspergillus species are ubiquitous organisms in the external environment, including soil, decaying matter, and air, in temperatures as high as 40 to 50° C. Aspergilli are easily isolated from houses, particularly from basements, crawl spaces, bedding, humidifiers, ventilation ducts, potted plants, dust, condiments (e.g., pepper), and marijuana samples. Aspergilli cause abortion in cattle and are important pathogens of marine organisms, insects, and domesticated and wild birds. Aflatoxin, which is one of the most potent carcinogens known, is produced by strains of *A. flavus* at ambient temperature on stored grain, spices, and nuts. Foodborne ingestion of preformed aflatoxin may cause hepatic necrosis or hepatocellular carcinoma (Chapter 181) in animals and humans.

Aspergillus species may be acquired from airborne conidia in inpatient and outpatient health care settings. Nosocomial aspergillosis is associated with building renovation, new construction, unfiltered air, contaminated ventilation systems, and fireproofing materials. Hospital water, which may become aerosolized during activities such as showering, also can be a potential source of aspergilli. As human pathogens, *Aspergillus* species may cause acute invasive disease, chronic infection, or allergic symptoms[1] (Table 311-1).

Acute invasive aspergillosis develops in immunocompromised patient populations, particularly patients with severe neutropenia (Chapter 153), hematologic malignancies,[2] hematopoietic stem cell transplantation (Chapter 163), severe aplastic anemia (Chapter 151), primary immunodeficiencies (Chapter 231), and solid organ transplantation, especially of heart, lung, and liver. Genetic deficiency of the soluble pattern-recognition receptor called PTX3 (long pentraxin 3) caused by homozygous haplotype (h2/h2) in the *PTX3* gene of donor cells leads to impaired neutrophilic antifungal capacity and an increased risk for invasive aspergillosis in recipients of stem cell transplants. Persistent neutropenia, corticosteroids, other immunosuppressive agents, graft-versus-host disease (GVHD), and cytomegalovirus disease are the most frequently observed clinical risk factors. Patients who have influenza
